PREFACE TO THE SECOND EDITION.

During the years I spent trying to get illustrations for the first edition of this book, I laboured under the great disadvantage — as regards my readers in England — of living abroad in countries where it was difficult or impossible to find many of the types of horseflesh, the photographic reproduction of which I knew was necessary for the attainment of the best result. Not being able to afford, from a monetary point of view, the luxury of a further postponement of publication, I issued the work, which was so kindly accepted by the public that the entire edition was exhausted within six months. Having by that time settled down in Melton Mowbray, I became aware that not alone were the illustrations in the book far from complete; but that, to do the subject justice, I required to renew my acquaintance with certain classes of English horses, and especially with hunters. Hence, instead of meeting the demands of the literary market by an immediate reprint, I continued my studies among horses for two years in Leicestershire and one year in Cheshire: hunting, breaking, training, and practising as a veterinary surgeon. All that time I kept the needs of a new edition in view, and received such great kindness from owners of horses and from owners of photographs of horses, that I am now able to present to my readers 142 new reproductions of photographs out of the 209 contained in the present edition. I trust that the new material I have been able to put in the letterpress will prove as useful as the additions to the illustrations.
I have enlarged the size of this book, and have re-arranged the photographs, so as to facilitate reference. The pictures of horses and other animals have been done, as nearly as possible, on a scale of \( \frac{1}{2} \).

For allowing me to photograph, or to use photographs of, their horses for this book, I have the honour to thank H.R.H. the Prince of Wales, Prince Henry of Pless, H.H. the Maharajah of Patiala, H.H. the Maharajah of Kooch Behar, Lady Sybil Tollemache, Lord Londonderry, Lord Belper, Lords Arthur and Lionel Cecil, Lord Marcus Beresford, the Hon. W. Anson, Sir Walter Gilbey, Captain Powell, Captain G. S. Williams, Mr. H. T. Barclay, Mr. Buckmaster, Mr. P. Crawford, Mr. C. G. Duff, Mr. John Gilmour, Mr. Helgesen, Mr. E. D. Miller, Mr. Tom Mitchell, Mr. E. Mucklow, junr., Mr. Munzt, M.P., Mr. John Parnell, Mr. J. E. Peat, Mr. H. C. Stephens, M.P., Mr. Joseph Wainwright, Mr. R. H. Walker, Mr. W. H. Walker, Messrs. John and James White, Mr. Horace Wolton, and other gentlemen. I beg to thank Professor Wallace (for the photograph of Queen of Trumps, which has appeared in his *Farm Live Stock of Great Britain*), the Shire Horse Society (for the photographs of Bury Victor Chief, Rokeby Harold, and Rokeby Fuchsia), the Suffolk Horse Society (for the photograph of Chieftain's Champion), Mr. Frank Haes, Mr. J. Cowell, Mr. R. Hotz, Messrs. Dixon & Sons, Mr. C. Reid, Mr. Clarence Hailey, Mr. W. A. Rouch, Messrs. Barraud, Messrs. Schreiber, Mr. C. Tadman, and Mr. H. R. Gibbs, for the photographs they have allowed me to use. A group in which the mare and foal in Fig. 352 is included, has been published in the *Badminton Magazine*. Figs. 237, 361, 362, 402 and 403 have appeared in *Modern Polo*.

*1st December, 1896.*
Much as Englishmen pride themselves on being good "judges" of a horse, the fact remains that exact ideas on the important subject of Conformation are current neither in the traditions of our "horsey" people, nor in our literature. The few English authors who have written on it, have done so in a fragmentary manner, and have contented themselves for the most part with laying down rule-of-thumb maxims for the blind acceptance of their readers. The French, on the contrary, have written on Extérieur, several elaborate books upon which they have expended an amount of scientific knowledge that does them infinite credit. It must be admitted that although they have proved themselves, in this respect, much superior in scientific research to our countrymen, their works seem to show that their experience has been gained more in the study and dissecting room, than in the stable and in the field. Both classes of authors, I venture to submit, have erred in trying to make general rules suitable to all kinds of horses, instead of pointing out that the standard of shape should, to a great extent, vary according to the work demanded. I may mention that illustrations of horses or of special "points" of these animals drawn without the aid of photography, having a bias difficult to be repressed, render the ideas of the artist more accurately than they portray the realities of nature.

In the attempt to conform to the requirements of truth, I have, as far as practicable, relied on photography for illustration. This art not alone gives exact representations, with marvellous minuteness of detail, but has completed the solution (begun by Professor Marey) of the once vexed question of the action of the horse's limbs during the various forms of movement, and has accordingly afforded us, in our present study, data which are as instructive as they are reliable. As I have written this book for non-scientific readers, as well as for those who desire to thoroughly master the subject; I have placed in small print the few chapters which I have devoted to the anatomical and mechanical details which were necessary to render the work complete. A perusal of the large print chapters will give a good general view of
the practical side of the subject, and, in most cases, the reasons for the opinions advanced. The information contained in the small print ones is, however, indispensable for the full comprehension of all the principles discussed, and, as it is of a very elementary character, I trust it will not be neglected. We must here remember that the horse is a living machine, the capabilities of which cannot be accurately gauged without a knowledge of its construction, and of the principles of its working. Having treated on Soundness and Age of Horses in another book, I have omitted these subjects entirely from the present one. I must, however, state that as they are directly connected with the question of a horse "standing" work, it is impossible to judge his capabilities with a near approach to correctness without a knowledge of veterinary science.

Besides the new features in this book to which I have already drawn notice, I may mention that I have tried to arrive at a knowledge of the respective "points" of speed and strength in the horse, by examining the conformation of other animals that are distinguished by the possession of one or other of these "gifts" in a high state of perfection. Also, I have made a more exhaustive enquiry into the nature of the paces and of the leap of the horse than has previously been attempted; my object being to obtain from it exact deductions as to the best kind of conformation for various forms of work.

At the suggestion of my friend, Veterinary Colonel Anderson, I began, about fifteen years ago, to write a book on the Points of the Horse, which subject I resolved to treat according to the time-honoured methods of my literary predecessors. I worked at it while studying to become a veterinary surgeon, and after that at Newmarket, where I went to reside in order to increase my knowledge of English thoroughbreds. For this, every facility was given me by my kind friends, Mr. John Hammond, Edwin Martin, Jarvis, Tom. Jennings, Junr., Alf. Sadler, R. Sherwood, and others, who were always glad to show me their horses, and discuss their various points. When the book was completed in 1883, I despatched the manuscript to my publishers by the hand of a friend, who, by an extraordinary piece of good luck, lost it so effectually that I have not seen it since. While suffering from the shock caused by the loss of the results of seven years' toil, I happened to read Professor Marey's Machine Animale (Animal Mechanics), and before I got half through it, I grasped the fact that I had been working in an entirely wrong groove, and that my careless friend had, most fortunately, saved me from publishing a book which would not have satisfied my more matured judgment. In 1884 I gave in London a short course of private lectures on the conformation of the horse
to some of the best known English artists. While endeavouring to convey instruction, I found great help from the use of a few photographs I had by me as illustrations, and accordingly determined to learn photography, and to utilise it in the preparation of the new book on the "shape and make" of horses which I had already begun, though on different "lines" to those on which the lost volume had been completed. On the following year I went abroad on a horse-breaking tour, and have spent the eight years which have elapsed since then in hard practical work (breaking, training for racing and chasing, and horse dealing) among horses in India, Burma, Ceylon, China, Japan, Egypt, South Africa, England and elsewhere. The facilities afforded by such an active and public life have enabled me to procure for this book a number of illustrations which it would have been impossible for me to have obtained under less favourable circumstances. No one who has not made the attempt oneself, can form an idea of the difficulty there often is in getting horses which have the required "points" (bad or good). For instance, I once examined 600 horses belonging to a dealer, and only obtained one specimen for my camera. Another time, a search through the troopers of two cavalry regiments was fruitless of results. For the photographs in this book, I have "run my eye" over certainly more than 10,000 horses! From this statement my readers will be able to form some idea of the extreme kindness and forbearance with which I have been treated by my horse-owning friends. Having obtained an animal with a required "point," the next thing to do was to photograph him, which frequently involved the expenditure of much time and trouble on account of the special character of the work.

Among the gentlemen to whom I am indebted for having granted me permission to have their horses photographed, I have the honour to number: His Grace the Duke of Westminster, Colonel Anderson, Captain Woolmer, Captain Mowbray of the Black Watch, Mr. W. H. Walker, Mr. A. A. Apclar, Mr. Tom. Jennings, Junr., Mr. Spooner Hart, Messrs. Milton and Co., Messrs. Ralli and Co. of Sydney and Calcutta, Messrs. Cook and Co., Mr. Oscar Dignam, Mr. E. Gregory, Mr. Vansittart, Mr. Steve Margrett of Melbourne, Mr. John Stevens of New Zealand, and Colonel Simpson. I am greatly obliged to Major Nott, Mr. Frank Haes, and Mr. Dixon, 112 Albany Street, N.W., for the negatives they have lent me; to Sir William Flower for allowing me to take photographs of Figs. 379, 380 and 381, in the South Kensington Museum; to Professor C. Stewart for similar permission with respect to Figs. 375, 383, 388 and 392, in the Museum of the R. C. S.; and to the Zoological Society for the loan of Figs. 363, 366 and 367. The action shown in the figures of the paces and of the leap has been adopted from the admirable
photographs done by Mr. E. Muybridge, and published in his *Animal Locomotion*; although the artistic "treatment" of the horses is original. This matchless American work is solely a collection of photographs, and does not contain any analysis of the movements of the horse. I may also mention that the photographs of Anschutz, on the same subject, are excellent.

In order to facilitate comparison, I have tried, as far as I have been able, to get the portraits of the horses, asses and zebras which are in this book, done to a uniform scale, namely, 1 to 20. I have added an index, which I have tried to make as easy of reference and as exhaustive as possible.

While strictly confining myself to the limits which bound the subject of Equine Conformation, I have had, while writing this book, the fortunate opportunity of throwing light on many points of horse knowledge which I have been, hitherto, unable to discuss in print. I therefore hope that the appearance of this work will help to complete what I have already written, in my books on veterinary science, riding, breaking, training and stable management; and that they and it will now form a useful horseman's library.

Without the skilful aid and kindly sympathy of the late Mr. J. H. Oswald Brown, I would not have been able to have finished this book, even in its present imperfect form. Since the year 1884 we laboured together on this subject. The pleasure in knowing that the work, after innumerable corrections and revisions, is at last done, has lost more than half its charm, from the fact that I cannot share it with him. He had finished the most of the illustrations before his sad and untimely death last autumn. The sketches which he left were completed by Mr. Frank Hobden, to whom I tender my best thanks.

POINTS OF THE HORSE.

CHAPTER I.

FIRST PRINCIPLES OF CONFORMATION.

Animals of Speed and Animals of Strength—Comparative Conformation—
Maey's Law

Animals of Speed and Animals of Strength.—When we speak of the conformation of a horse, we refer to the adaptability of his body for general or special work. We all know, without the aid of science to tell us, that a light-boned thoroughbred would be as unsuitable to carry a fifteen-stone man, as a thick-set cob would be to win a five-furlong race. The "weed" would not fail, necessarily, from deficiency in weight of bone and muscle, for there are many ponies of thirteen hands or under, which would weigh no more than the slender T. Y. C. performer, and yet could bear the welter burden through a long day's journey, with ease to themselves and comfort to their rider. The failure to carry weight in the one case, and the inability to display a high degree of speed in the other, would obviously be due (in the absence of any particular defect) to the fact of the conformation of the animal not being suitable to the kind of work to which he was put. In our study of the "make and shape" of horses, we may profitably begin by taking a comparative view of animals of great speed and those of
First Principles of Conformation.

immense strength, so as to arrive at a knowledge of the principles by which their special characteristics are developed to a high degree of excellence. As the conformation best adapted for the one is different from that for the other, we cannot find both united in the same animal. I need hardly say that the manner in which the proportions of speed and strength are varied in each particular horse, is the measure of the suitability of the animal to the kind of work it is called upon to perform. Thus, a dray-horse which can trot a mile in eight minutes with 3,000 lbs. behind it, may be quite as useful, in its own way, as a match-trotter which, with a sulky and driver weighing together 200 lbs., can do a mile in two minutes twenty seconds.

Comparative Conformation.—In this proposed research, we shall find that the two classes (those of speed and those of strength) to which I have just alluded, differ essentially in shape from each other, and that individuals of each respective class have a similar kind of conformation. As an example of the gallopers, let us take the Indian black buck (Fig. 1), which, for half a mile, could give five hands and a beating to the fastest horse that ever looked through a bridle. Then there is the cheetah (Fig. 3), which can give the antelope 100 yards start and catch him in a furlong. It is true that the spotted cat effects his purpose a good deal by surprise; but it is equally certain that for a couple of hundred yards he can travel with the velocity of an express train. Also, there is the greyhound (Fig. 8), with whose speed we are all familiar. In comparison with these fleet of foot animals, let us note the "make and shape" of the buffalo (Fig. 2) and rhinoceros, both of which are endowed with vast muscular power. And as the opposite of the "long-tailed dog," let us take the bulldog or dachshund. On examining these animals we shall observe that the limbs (especially the hind ones, from which is derived the greater part of the forward propulsion) of the gallopers are much longer in proportion to the animal's
Fig. 1.—Indian Black Buck.

Fig. 2.—Indian Buffalo.

To face p. 2.
height than those of the representatives of strength. We see this fact best illustrated when we compare individuals of the same species or family, like the greyhound and bulldog, or the cheetah and tiger (Fig. 5), which is the strongest member of the cat tribe. A greyhound and a typical race-horse (compare Fig. 8 with Fig. 9) possess many points in common. We also obtain good examples among horned cattle, in the Indian trotting bullock (Fig. 6), and the Indian heavy draught bull (Fig. 7), whose sex is indicated by the large size of his hump. Special length of hind limb is well shown in the hare and in the lynx (Fig. 4), both of which are animals of great speed. As it is not the custom to breed men with reference to their physical development, we do not find the difference in question so well marked in them as in the lower animals. Yet, for all that, we may note among "sprinters" and wrestlers the working of this principle. I may explain that the muscles of the limbs of the horse, ox, buffalo and antelope do not, practically, extend below the knees and hocks (being continued by tendons from these joints); but in the dog and cat tribe, they go down to the foot.

From the examples cited of animals of great strength and those of high speed, we may conclude that the former are distinguished by a long body and short legs; and the latter, by a short trunk and long extremities. I am here assuming that the length of the body is taken comparatively with that of the legs, and without reference to the proportions of the body itself.

We may also observe from the photographs before us, that the limbs of speedy quadrupeds are proportionately as slender as they are long, and that those exhibiting strength are as thick as they are short.

I may explain that muscles are the active and essential part of the machinery used by animals in locomotion, bones being merely passive agents. In fact, there are myriads of the lower animals which move about with considerable speed by means of their muscles, but which have no bones of any kind.
Marey's Law.—The foregoing observations will prepare us for the law cited by Marey in his book, *La Machine Animale*, which states that muscles of speed are long and slender, and those of strength are short and thick. This distinguished Frenchman gives as instances the long breast-bones of birds—such as snipe and partridge—which can move their wings with great rapidity, and the short ones of hovering birds—such as the eagle and albatross—which can overcome the immense resistance of the air upon which the large area of their pinions presses, only with slow, but very powerful strokes. The expanse of the outspread wings of birds of quick stroke—such as wild pigeon and partridge—is of far less comparative size than is that of those of hovering birds. The relative speed with which these birds can cleave the air does not, of course, affect the question of the form and action of their muscles.

I may remark that the foregoing principles govern the conformation of horses as closely as they do that of other animals. I shall, however, defer their application to horses till further on, when we shall have acquired a certain amount of exact knowledge of the physical conditions of the horse, which will greatly aid us in drawing accurate conclusions as to his "shape and make."

CHAPTER II.

STRUCTURES OF THE BODY.

The frame-work of the body consists of the skeleton (Fig. 12), which is composed of a large number of connected bones that are moved by muscles. We should, generally, regard differences of length in the limbs, as those of muscles, rather than of bones; for the former are the producers of all movements of progression, the latter aiding only in the application of the force exerted.

Bones.—The chief duties of bones in the act of progression are—(1) to bear weight; (2) to resist the effects of concussion; and (3) to act as levers. Capability for performing (1) and (2) is dependent on conditions of texture ("quality"), size ("substance"), and arrangement.

Quality and substance of bone.—Whether the animal be intended to carry heavy burdens, or to gallop over hard ground, it is always a matter of the greatest importance that his bones, especially those below his knees and hocks, should be of strong and compact texture. It has been customary to state, in a vague way, that the bones of Arab horses and English thoroughbreds are denser than those of other breeds. It would, however, be more exact to say that the drier the soil on which a horse has been bred and brought up, and the "harder" the food upon which he has
been fed, the better will be the quality of his bone; for we find that in dry, hot climates in the East, native ponies, which can have little or no admixture of Arab blood, have legs as clean and hard as any that are to be met with in the Desert. We need not test our theories on this subject by the microscope, or by determining the specific gravity of various sections of bone taken from different animals; for we can obtain a far more reliable and practical proof from the fact that, other things being equal, the more porous are bones, the more liable are they to bony deposits, such as splints, spavins, and ringbones. I here purposely omit to add "sore shins;" for this disease is more or less peculiar to immature thoroughbreds that are put into training at an age much earlier than that at which ordinary horses are broken. The nature of a horse's hoofs, which can always be determined by inspection, or by using the "drawing knife," will generally afford us a safe guide by which to judge of the quality of his bone. Thus we find that animals which have been reared amid damp surroundings and on succulent food, will, as a rule, be prone to bony enlargements, and will have flat feet of soft horn. We cannot fail to notice this if we compare the horses of the English fen counties with those bred on high, dry land; or animals raised in the arid plains of the Punjab and Deccan, with those of swampy Lower Bengal. Hence, if, when judging an animal about the history of which we know nothing, and which does not appear to have undergone enough work to test the soundness of his legs, we find that he has weak, flat hoofs, we shall not err, in the large majority of cases, by concluding that his bone is of inferior quality. Although dryness of climate is always a favourable condition for horses; excessive heat diminishes the size of the bone of the indigenous animals: a circumstance which may, to a great extent, account for the fact that horses bred in tropical climates, however hardy and wiry they may be, are very rarely of a weight-carrying type.

The popular term "bone" refers to the size of the bones below the knees and hocks, as compared to the weight they
Fig. 6.—Indian Trotting Bullock.

Fig. 7.—Indian Heavy Draught Bull.
have to carry. As the limbs of the domestic horse, especially when used at fast paces and when jumping, have far more strain put upon them, than if the animal were in a wild state; the judicious breeder will try to obtain as much "bone" as possible. This necessity is inculcated by the proverbial saying that "a horse is as old as his legs." The bones of the limbs, like tendons and ligaments, may be looked upon as adjuncts to, or component parts of, their muscles, which are the active organs of movement. All these structures are dependent for their development on the blood supply, which is increased by exercise. Thus, continued idleness causes the bones, tendons and ligaments of the legs to become abnormally liable to injury. Also, in cases of paralysis of a limb, the bones, as well as the muscles, waste. Hence, when judging of a horse's capacity for standing work, we must not confine our attention to his "bone," without also considering the condition of his muscles, tendons and ligaments. In making practical observations on horses, we may often be greatly assisted in our investigations by judging of the muscles by the bones, and vice versa. Thus, if we see an animal in poor condition which has been brought on by hardship or want of food, we may, by the appearance of his "bone," form a good idea of what his muscles will be when he "fills out." Even when a horse is "fit and well," a display of large, well-shaped bone (of the body as well as of the limbs) should dispose us to consider that his muscles are more powerful than they appear at first glance. I was much struck by this fact when I had the pleasure of closely inspecting the celebrated St. Gatien, whom Mr. John Hammond very kindly showed me in his box, some time before he ran his dead heat with Harvester for the Derby of 1884; for I was greatly "taken" with the sight of the large, symmetrically formed bones of his legs, his long back ribs, and his well-developed pelvis, the inner angle of which was so prominent as to make a distinct "rise" in the outline of his croup; not to mention his long, sloping shoulders, and immense gaskins. On the
other hand, if we observe that an animal which is in "dealer's condition" is light of bone, we may, as a rule, conclude that there is not very much muscle in the load of meat which he carries. Among sound, good horses, "Mr. Morton's" Dalmeny was one of the lightest below the knee I have ever seen; but no exception could have been taken to him on that account, for his legs had no superfluous weight to carry, and his muscles were of the long slender type, which is generally characteristic of the possession of speed. I need hardly say that the bones and muscles of the limbs are not always in keeping with those of the body; for we daily see instances of animals that are too heavily "topped" for their legs.

Men of experience know that a horse should have plenty of "bone" in order to be able to carry weight with ease to himself for long distances and at comparatively fast paces—as, for example, when hunting. If we take two horses that can perform about equally well in a long run with a similar welter weight up, one having the "pull" in speed, the other in bone and muscle, we shall usually find that the latter will not feel the effects of the work so much as the former. I may explain this on the reasonable supposition that the weight-bearing muscles of the lighter-built horse, not being so strong as those of the "heavier" animal, will naturally become more fatigued. The objection sometimes advanced against thoroughbreds for hunting, that they cannot "come out again" as quickly as half-bred animals, is valid only when the former are lighter built than the latter; for, if blood horses of equal bone and muscle were obtained, the difference would be all the other way.

Large muscles, as we have seen, require large bones. It also goes without saying that the more are bones exposed to the effects of concussion, the denser and stronger should they be. Consequently, we may conclude that the lighter an animal's body is, in comparison to the strength of its component parts and the amount of its muscular force, the greater will be its powers of rapid progression. Hence we
Barrauds, Liverpool.

Fig. 8.—Mr. G. F. Fawcett’s Fabulous Fortune (Winner of the Waterloo Cup, 1896) and his trainer, T. Wright.

Fig. 9.—The Duke of Portland’s St. Simon.
find that the race-horse, like all quadrupeds of which speed is the chief characteristic, has comparatively slender bones of extremely dense texture, and that his muscles are particularly strong for their thickness. Owing to the law of compensation, which governs the conditions of animal life, it is almost impossible to obtain bone of great volume, and, at the same time, of the finest quality. On this account, as size is indispensable with the cart-horse, we endeavour, with him, to obtain large bone of sufficient strength to meet his requirements. In the intermediate classes of horses, the relations between volume and quality should be judged according to the nature of the work in view.

Arrangement of bones.—The relative position which bones occupy with respect to each other affect their leverage, weight-carrying, and concussion-resisting powers—conditions which will be treated in detail when we consider the various points which they affect.

Cartilage.—Cartilage or gristle is a strong, flexible, bluish-white substance which is found in connection with bone, and of which there are various kinds. Articular cartilage covers the ends of bones that form movable joints. Temporary cartilage is bone in a transition form. The ribs are connected to the breastbone by cartilages which form elastic prolongations. Cartilages also are interposed between the bones of various joints in order to connect or protect them. The cartilage of prolongation forms an elastic continuation of the top of the shoulder-blade.

Muscles and Tendons.—The animal's moving power is derived from muscles, which form the lean of meat, and which, as a rule, are attached to bones. Muscles act by virtue of the property they possess of being able to shorten themselves on being stimulated by the nervous system. Thus, if we wish to raise, say, our right hand to the shoulder, our brain telegraphs, so to speak, the order, by means of the
nerves, to the *biceps* muscle, which is attached at one end to
to the shoulder-blade, close to the shoulder-joint, and, at the
other, to the bones of the fore arm, a little below the elbow.
Hence this muscle, on contracting, draws the hand up in the
required direction.

As muscles are built up of contractile fibres, their
strength, other things being equal, is proportionate to their
thickness.

In order to economise space, muscles are generally
attached to bones by means of *tendons* (sinews), which are
hard, fibrous cords of great toughness. The tendon at one
extremity is firmly united to the end of the muscle, and, at
the other, to the bone.

We find from experiment that a muscle can contract to
about two-thirds of its ordinary length, which is, therefore,
proportionate to the extent of movement it is capable of
producing. If the muscles which move the limbs be com-
paratively short, the stride will also be short, and the
horse will be slower than he would otherwise be, no matter
how thick and powerful are his muscles. We may, there-
fore, conclude that speed is associated with length of
muscle, as has been stated on page 4.

As length of muscle is necessarily accompanied by
length of bone, we may judge of the former by the latter,
which can usually be readily estimated.

The "give and take" principle, which applies more or
less to all created things, holds good with muscles. Hence,
in the race-horse, for which the possession of speed is the
chief essential of success, we should seek the greatest
possible length of muscle, with just sufficient strength to meet
his requirements for carrying weight and for sustaining the
exertion he may be called upon to undergo. In the cart-horse,
on the contrary, thickness of muscle is the great desideratum,
always supposing that he has sufficient activity to walk well
and on occasion to trot at a moderately brisk rate. As a thin
muscle will contract at least as quickly as a thick one of the
same length, it follows that an increase in the thickness of
muscles is useful only in making the work more easy, and that it does not otherwise add to the speed. Massive muscles, compared to slight ones, have two disadvantages, namely—they add to the weight to be carried, both in muscle and bone; and they necessitate the possession of large joints, which, from increased friction, are not so easily bent and extended as smaller ones; besides this, it has been proved that they do not respond as quickly to nervous stimulus. Although it is impossible to lay down any exact rules on this subject, we may say, speaking generally, that the thickness of muscle which would be commendable in a weight-carrying hunter, would be quite out of place in a race-horse, as we may see by comparing Fig. 288 with Fig. 289. We may often observe that race-horses which were very smart as two-year-olds, lose their "form" after that age without any assignable reason except that as they "thickened," they got slow. I may remark that those speedy animals, the cheetah, greyhound, and antelope, like the race-horse, are comparatively narrow behind, and that the hind-quarters of the cart-horse are very wide. The muscular development to be sought for in the race-horse, in order to enable him to carry weight (within racing limits) and to stay, should be obtained with a minimum increase to the burden the animal has got to move; and is to be looked for chiefly in the loins, gaskins, and fore arms, with great rotundity and comparative length of the back ribs, and comparative thickness of bone just below the hocks. In this respect, Ormonde, St. Gatien, Bendigo, Isonomy, Barcaldine, and Carbine (the New Zealand son of Musket), for example, were all muscular horses. St. Simon (Fig. 9) was a notable example of a horse of the highest class being of remarkably light build. He had, however, marvellously good shoulders and loins.

We know from experiment that muscles of the same thickness are stronger in animals of one species than they are in those of another kind; and we may reasonably infer that even among individual horses the same rule holds good. In fact, we may take for granted that the "quality" of
muscle, tendon and ligament, as well as of bone, is better in some horses than in others; the great factors in producing strong tissue appearing to be: heredity; residence in a dry, warm climate; "hard" food; exercise; and Eastern blood.

**Ligaments.**—The ends of the bones that form joints are held together by white ligaments, which are similar in structure to tendons; but, unlike them, they serve to connect bones with bones, and, in a few cases, bones with tendons. They have no direct connection with muscles. There are, also, yellow ligaments, which, being elastic, aid in supporting weight without fatigue to the animal.

**Connective Tissue.**—The skin, which covers and protects the body, is largely composed of a strong, fibrous structure called connective tissue, which, proceeding inwards from the skin in the form of, more or less, thick layers and bands, furnishes a supporting network for the component parts of the other tissues. Thus, if we compare a slice from the under-cut of a sirloin of beef with one from a round of beef, we shall see that the relative coarseness of grain of the latter is due to the thickness of the layers of connective tissue which run through it. As connective tissue has only the passive action of support, I need hardly say, that the coarser in grain a muscle is, the less powerful will it be; although it will be better able to resist the effects of external violence than one of finer grain. The protective duty of connective tissue, as regards muscles, may be readily inferred from the fact that the less exposed muscles are to injury from without, by reason of their position, the less connective tissue do they contain. This tissue, also, forms ligaments and tendons, and ensheathes bones, cartilages, nerves, etc. There is always a large amount of it immediately underneath the skin, in the form of loose fibrous sheets, as we may see in the dead animal. The presence of a great quantity of it in this position will, naturally, cause the underlying parts to be ill-
defined, a fact which will be especially noticeable about the tendons and ligaments below the knees and hocks, owing to the absence of muscle about these parts. We may, therefore, draw the following deductions: (1) That, as the thickness of the skin is a measure of the amount of connective tissue it contains; the thicker the hide, other things being equal, the more connective tissue will there be in and about the muscles. (2) That, as its action is only passive, the more of it a muscle contains, the slower will be the movements of the muscle. Hence, we may reasonably conclude that the fact of a horse having a thick skin, and, for instance, ill-defined suspensory ligaments, owing to natural "fleshiness," would warrant us in supposing that he was deficient in speed. I may remark that, with age, the amount of connective tissue in the body greatly increases. As Guérin states: "In the old man, the tendon seems to invade the muscle, so that the portion of the calf of the leg which remains is placed very high, and is much reduced in length. The muscles of the loins and back present the same character. In old age they are poorer in red fibre, but richer in tendon."

The component parts of the body which, respectively, have the same structure, are called tissues. Thus we have bony tissue, consisting of bone; muscular tissue, of muscle; nervous tissue, of nerve substance; connective tissue, of white fibrous material; and so on.

The Nervous System.—While considering the form of the horse from a mechanical point of view, we must not lose sight of the marked differences which exist in the nervous system of various animals, and which greatly heighten, or may altogether nullify, advantages obtained from good conformation. We are aware, speaking within reasonable limits, that the amount of contraction—i.e. force—exhibited by a muscle is proportional to the degree of stimulation given by its nerves. As the nervous system of some animals acts far more energetically than that of others, it follows that the former, other things being equal, will be stronger than the
latter; although no difference in conformation, or in development of muscle, may be perceptible. Not alone does the amount of nervous force differ much among animals of the same kind; but some individuals of the same species can stimulate their muscles by means of their nerves quicker than their fellows. We see this well exemplified in adepts at fencing, cricket, boxing, and other kindred sports; at which, so-called quickness of eye is all-essential. I may mention that the brilliant bat, or accomplished maître d'armes, apart from the possession of the necessary amount of knowledge, judgment, and physique, excels because he has the gift of moving his muscles, in response to the stimulus received by the nerves of his eyes, quicker, as well as in more accurately regulated style, than ordinary men. This assertion is in no way based on mere theory; for we find that among men whose duty it is to record (as in observatories) the exact moment at which they see certain phenomena occur, it is necessary, in order to avoid error, to allow for the difference in time these men, respectively, take; although it may only be a fraction of a second. To do this, it is requisite to obtain, for each man, his "personal equation," as it is termed. We can, therefore, conclude that speed and strength are as dependent on the nature and quality of the nervous system as they are on conformation and muscular development. It also goes without saying that a horse may possess every physical excellence, and yet be worthless on account of having a "soft heart," or bad temper.
CHAPTER III.

NAMES OF EXTERNAL PARTS AND DEFINITIONS.

Head—Neck—Breast and Chest—Shoulders—Withers—Elbow—Fore Arm
 —Knee—Cannon—Fetlock—Pastern—Hoof—Back—Loins—Ribs—
 Plank—Belly—Brisket—Croup—Thigh—Gaskin—Hock—Dock—
 Height of a Horse—Length of the Body of a Horse—Depth of Chest
 at Withers—Depth of Body—Height at Croup.

As the external parts and regions of the body do not, in
many cases, admit of very accurate definition, I crave the
indulgence of my readers in this attempt to mark out their
positions and boundaries. I have omitted mention of some
parts which, being known to every one, require no expla-
nation. The figures and letters employed in the following
list have reference to those on Fig. io.

**Head** (1).—Looking at the horse in profile, we may
regard the head as being divided from the neck by a line
proceeding from the back of the ear, along the rear edge of
the lower jaw to its angle.

The *forehead* (a) forms the upper part of the face. It
extends down to a line joining the inner angle (*canthus*) of
each eye, and reaches as high as the fore-lock and the base
of the ears.

The *fore-lock* is a tuft of hair which lies between the ears,
and is a continuation of the mane.

The *temples* are those portions of the head, on each side
of the forehead, which lie between the ear and eye.

The *nose* (b) is a continuation of the forehead, and ends
opposite the nostrils at the angle (c) formed by the line of
the face and the line of the muzzle.
The *muzzle* is the lower end of the head, and includes the nostrils, upper (\(d\)) and lower lip (\(e\)), and the bones and teeth covered by them.

The *bars of the mouth* are the bare portions of the gums of the lower jaw which lie on each side, between the back teeth and the tushes, or the place usually occupied by the tushes.

The *chin-groove* (\(f\)) is just under the bars of the mouth.

It is the smooth and rounded under part of the lower jaw, in which the curb chain should rest when a curb bit is used.

The *angles of the lower jaw* (\(g\)) are the bony angles between which the upper end of the wind-pipe lies.

The *branches of the lower jaw* run from the chin-groove to the angles of the lower jaw.

The *occipital crest* is the bony prominence which constitutes the top of the head, and which more or less rises between the ears. It is particularly high in the head shown in Fig. 254.
The Neck (2) is separated from the shoulders by a line which goes from the dip that is just in front of the withers, to the depression which is made by the union of the neck and breast.

The poll (p) is the part which is on the top of the neck and is immediately behind the ears.

The crest (t) is the upper part of the neck, extending from the withers to the ears.

The jugular groove (u) is the groove which is on each side of the neck, just above the wind-pipe. It is well shown in Fig. 230.

Breast and Chest.—Among horsemen who are unacquainted with anatomy, the latter of these two terms is frequently used to express the former. At the risk of employing a word contrary to colloquial custom, I would suggest that the term “chest” be applied exclusively to the cavity which occupies nearly the front third of the trunk, and in which the lungs and heart are situated. It is divided from the belly (abdomen) by the diaphragm (Fig. 13).

Shoulders (3).—The line of union between the shoulders and the neck is well shown in the majority of harness and draught horses; there being, in such cases, a distinct depression immediately in front of the shoulder. In well-shaped saddle horses, this dip between shoulder and neck will be more or less difficult to find. The withers form the upper boundary of the shoulder. The rear border of the shoulder may be taken from behind the “swell” of the muscle which is just below the withers, to the elbow.

The point of the shoulder (h) is the prominent bony angle, on each side of the chest, a little below the junction of the neck and shoulder.

The Withers (4) are the bony ridge which is the forward continuation of the back. Its posterior limit is, as a rule, ill-defined; for the curve made by the withers usually runs into that of the back in a gradual manner. Its anterior
termination can generally be easily felt by the fingers; as this bony ridge ends abruptly in the crest.

The Elbow, which is a portion of the fore arm, is the large bony projection at the upper and posterior part of the fore arm. The point of the elbow (i) is the top of this bony projection.

The Fore Arm (5) is placed between the shoulder and knee. Its upper boundary may be taken as a horizontal line drawn across the fore limb, just below the lump of muscle which is at the bottom of the shoulder.

The castors, corns, or chesnuts (k) are the horny growths which are, respectively, above the knees, and just below the hocks, on the inside of the legs.

Knee (6).—The upper boundary of the knee may be regarded as a line drawn at right angles to the direction of the leg, above the knee joint, and just clear of the bony prominence that is on the side of the knee. The lower boundary of the knee may be taken as a line joining the point where the line of the cannon-bone meets that of the knee, with that where the line of the back tendons is terminated by the bone (the trapezium, l) which is at the back of the knee.

The Cannon (7).—A suitable designation for the part of the leg which is situated between the knee and fetlock is much required. The term “cannon” is apt to give one the impression that only the cannon-bone is meant: it would be more convenient if the back tendons and suspensory ligament were also included. The line dividing the cannon from the fetlock is one drawn across the leg immediately above the prominence caused by the fetlock joint.

The back tendons (m) or back sinews are the fibrous cord which runs down the back of the leg between the knee and the fetlock. This cord consists of two tendons which lie closely together.

The suspensory ligament is a fibrous cord which lies
between the cannon-bone and the back tendons, and which can be seen in a well-formed leg that is not unduly covered with hair (Fig. 292).

The cannon-bone (f) is the bone which lies between the knee and the fetlock. It has two small bones (outside and inside splendid bone) at its back.

**Fetlock** (8).—The fetlock joint is the joint which the cannon-bone makes with the pastern. The term fetlock (i.e. foot-lock) signifies the tuft of hair that usually grows behind this joint, and also the joint itself and the enlargement made by the bones which form it.

**Pastern** (9).—This is the short column of bones which is placed between the fetlock and the hoof.

The hollow of the pastern is the hollow at the back and lower part of the pastern.

The coronet is the comparatively soft lower portion of the pastern which is immediately above the hoof.

**The Hoof** (10) is the horny box which encloses the lower part of the limb. The front part of the hoof, near the ground surface, is called the toe; the side portions, the quarters; and the rear parts, on the ground surface, the heels. The outer portion of the hoof is termed the wall, which is divided into a hard, fibrous outer covering called the crust, and a soft inner layer of non-fibrous horn. The designations “wall” and “crust” are often used indiscriminately.

The frog is the triangular buffer which is in the centre of the ground surface of the hoof.

The cleft of the frog is the division in the middle line of the frog. In healthy feet, it consists of only a slight depression.

The bars of the hoof are the portions of the wall of the hoof which are turned inwards at the heels, and run more or less parallel to the sides of the frog. The sole is that portion
of the ground surface of the foot which is included between the wall, bars, and frog.

**Back** (11).—Anatomically speaking, the back consists of that portion of the spinal column to which the ribs are attached, and it consequently includes the withers; but not the loins. The term "back" is, in common parlance, an ill-defined region. Some regard it as consisting of the whole of the upper line of the body, from the front of the withers to the root of the tail. Others would exclude from this the croup. Probably, the majority of horsemen would say the back of a horse is included between the highest point of the croup and the commencement of the withers. For convenience sake I shall adopt the anatomical definition, with the omission of the withers, which have separate functions, and which I shall consider by themselves. I may, therefore, state that the back is bounded in front by the withers; behind, by the loins; and on each side, by the ribs.

**The Loins** (12) are placed between the back and croup, at front and rear, with the flanks on each side. We may regard the loins as that portion of the spinal column which is devoid of ribs, and which is in front of the highest point (*posterior iliac spine*, Fig. 12) of the pelvis.

**The Ribs** (13) are bounded by the shoulders in front, by the flanks behind, by the back above, and by the belly and brisket (*sternum*) below.

**The Flank** (14) is that part of the side of the horse which is free from bone and which thinly covers the intestines. It is placed between the loins above, the ribs to the front, the thigh and point of the hip to the rear, and the belly below.

The *hollow of the flank* is the upper portion of the flank, which is bounded above by the loins, and below by a line joining the end of the last rib with the lower edge of the point of the hip.
The Belly (15) or abdomen is the large cavity (Fig. 13) which contains the stomach, liver, spleen, intestines, kidneys, bladder, etc. The term "belly" is applied, in common phraseology, to the underneath portion of the body which is not covered by bone.

The Brisket (16) is the lower part of the horse's chest. The girth place is the rear portion of the sternum (breast-bone) which is just behind the fore legs, and underneath which the girths pass when the horse is saddled.

The Croup (17) is that portion of the upper part of the body which is situated between the loins in front and the tail behind. Roughly speaking, it may be said to extend down, on each side, to a line drawn from the lower edge of the point of the hip, to the point of the buttock.

The point of the hip (s) is the bony surface, more or less prominent, which is a little to the rear of the last rib. It is the anterior point of the pelvis.

The point of the buttock (o) is the bony prominence which is the rearmost point of the pelvis. It is a few inches below the root of the tail.

The Thigh (18) is bordered by the stifle, flank, croup, buttock, and gaskin, from which it is separated by a horizontal line drawn from the upper end of the straight line made by the hamstring or tendo Achillis (p), which proceeds towards the thigh from the point of the hock (g). I am aware that this definition is far from being anatomically correct, but it is one which fairly represents the acceptation of the term among horsemen.

The Stifle (n) is the joint of the hind leg which is at the lower part of the flank.

The Gaskin (19) is situated between the thigh and the hock, from which it is divided by a line drawn from the point of the hock, clear of the bony prominences of the joint.
The Hock (20) is placed between the gaskin and the hind cannon-bone, from which we may separate it by a line drawn across this bone at the point at which its head begins to enlarge in order to form a joint with the lower bones of the hock.

The point of the hock (q) is the bony projection at the back and top of the hock.

The parts of the hind leg below the hock are similarly named to those of the fore leg below the knee.

The Dock (r) is the solid part of the tail.

N.B.—The following definitions have reference to Fig. 11:

The Height of a Horse (a b) is the vertical distance of the highest point of his withers from the ground, when he is standing with his fore legs nearly vertical and with the points of his hocks in a vertical line with the points of his buttocks. I have qualified “vertical” with “nearly” when referring to the fore legs, for when the hind legs are placed as in Fig. 11, the weight of the head and neck, which are in front of the fore legs, would cause the animal to stand somewhat “over.” I may mention that this figure was drawn from a photograph of a well-shaped race-horse, Tristan, who was standing, if I may use the expression, “at attention.” When a pony is being measured for racing, his legs should be placed in the position I have described.

The Length of the Body of a Horse (d e) is the horizontal distance from the front of the chest to a line dropped vertically from the point of the buttock. I must explain that this measurement is a somewhat arbitrary one; but it is, as far as I can see, the best for the purpose.

Colonel Duhousset, in his book, *Le Cheval*, takes the length of a horse as the distance from the point of the
shoulder to the point of the buttock. As this is not a horizontal measurement, I prefer to it the one I have just given

The Depth of the Chest at the Withers \((a\ c)\) is the vertical distance from the top of the withers to the bottom of the chest. This measurement, being taken for convenience sake, is an arbitrary one; for the chest is lower between the fore legs than behind the elbow, which is the spot I have selected. Besides this, the actual height of the withers above the roof of the chest has no fixed relation to the depth of the chest.

Depth of the Body \((f\ g)\).—The best and most uniform point to take this is, I think, the lowest point of the back.

Height at the Croup \((h\ i)\) is measured from the highest point of the hind-quarters.
CHAPTER IV.

SKETCH OF THE ANATOMY OF THE HORSE.

Definitions.—When one bone unites with another bone, or with a piece of cartilage, to form a joint, it is said to articulate with it. The term articulation is used as a synonym for joint.

A ball and socket joint is formed by the head of one bone resting in a cavity of another bone. The more shallow the cavity, the more extensive will be the power of movement. The horse’s shoulder joint and hip joint are good examples of this kind of articulation. A hinge joint is one which works only by extension and flexion, like the horse’s knee.

“A limb,” as Professor Huxley states, “is flexed when it is bent; extended, when it is straightened out.” We may adopt this definition, with the exception that the fetlock joint becomes bent when it is extended, and straightened out when it is partly flexed.

The word dorsal is used with reference to things of, or belonging to, the back, which, anatomically, is limited to that portion of the spine which is connected with the ribs.

If a muscle is attached, by one end, to a bone which it can move, and, by the other end, to one which is fixed, the former is called the insertion of the muscle; the latter, the origin. Thus, the origin of the biceps in man (p. 10) is near the shoulder joint; and its insertion is on the bone of the fore arm. When a muscle, on contracting, can move the bones at both its ends, the points of connection are called attachments; an expression which is also applied collectively to the origin and insertion. I may mention that muscles are not invariably attached to bones, but may, on the contrary, be connected to cartilages, ligaments, to the fibrous covering of muscles, or even to the skin.

Bones.—The skeleton is composed of the limbs and spinal column, which consists of the head, vertebrae, ribs, and breast-bone (Fig. 12). A vertebra is one of the short bones which, when united, form the column of bones that extends from the head to the end of the tail. There are seven vertebrae of the neck, eighteen of the back, six of the loins, five of the croup
BONES.

(or sacrum), and from thirteen to twenty of the tail. All the vertebrae, except those of the tail, have a canal in which the spinal cord lies. They are united one to another with more or less power of movement, except those of the croup, which, in the grown-up horse, form one solid bony mass. The head may be said to be composed of vertebrae in a peculiarly altered shape.

The withers are the long spines of the seven or eight dorsal vertebrae which come after the first. Generally speaking, the better bred a horse is, the further to the rear do the withes extend. The spine of the fifth dorsal vertebra forms the summit of the withers.

There are eighteen ribs—eight true and ten false—attached to the dorsal vertebrae. Both kinds have pieces of cartilage attached to their lower ends.

The true ribs are connected by their respective cartilages with the breast bone; but the false ones are only indirectly connected to it, the cartilage of the first false rib resting on that of the last true one, that of the second false rib on the first false one, and so on.

The fore limb consists of the shoulder blade, humerus, bones of the fore arm, bones of the knee, cannon-bone, splint bones, long pastern bone, short pastern bone, pedal (or coffin) bone, two small bones at the back of the fetlock, and the navicular bone, which lies at the back of the joint formed by the small pastern bone and the pedal bone.

The shoulder blade (or scapula) is a broad, thin bone, which is flat on its inside surface and has a narrow ridge of bone (the spine of the scapula) on its outer surface. This spine serves as a partition to divide the muscles which extend the shoulder joint from those that flex it.
There are two bones of the fore arm, namely, the radius, which makes a joint with the humerus and with the bones of the knee; and the ulna, which is united to the back and upper part of the radius, above which it projects. The free part of the ulna is called the **olecranon**, the top of which is termed the **point of the elbow**.

There are two rows of bones of the knee, at the back of which a bone (the **trapezium**) is placed. It is curved inwards so as to form a groove for the passage of the back tendons of the fore leg.

The two **splint bones** are placed at the back of the **cannon-bone**, one on the outside, the other on the inside. They form a groove in which lies the upper portion of the **suspensory ligament**.

There is a joint between the cannon-bone and the **long pastern bone**, between the two pastern bones, and between the **short pastern bone** and the **pedal** (or **coffin**) bone. The **navicular bone** articulates with both the short pastern bone and the pedal bone. It and the two bones behind the fetlock (the **scoamoid bones**) serve as pulleys for one of the back tendons.

The pedal bone is surrounded by a membrane, which secretes the horn of the wall of the hoof, sole and frog, in somewhat the same manner as the skin which covers the bones of the head secretes the hair of that part.

The **pelvis**, which rests on, and is firmly attached to, the sacrum, appears as a single bone in the adult animal, although it really consists of two halves, which we may regard as the respective shoulder blades of the hind-quarters. Each half furnishes a socket for the head of its respective thigh bone. The **point of the hip**, on either side, is the front and outer corner of the pelvis. The two inner corners of the pelvis are firmly connected with the sacrum, upon which they rest. They form the highest point of the bony framework of the croup. In the absence of a recognised popular term, we may call the rearmost points of the pelvis the **points of the buttock**.

The head of the thigh bone makes a ball and socket joint with the pelvis; while its lower end articulates with the tibia to form the stifle joint, in front of which the **patella** (knee cap) is placed. The patella serves for the attachment of muscles which extend the stifle joint. It is kept in position by strong ligaments. A portion of the thigh bone projects, from the outside, above the hip joint. The **tibia** articulates, at one end, with the thigh bone; and, at the other, with the **astragalus**, which is one of the bones of the hock. The part of the astragalus which makes a joint with the tibia, is formed like a pulley, the grooves of which have an outward and forward direction. The **os calcis** is placed behind the astragalus, and projects above it; its summit being called the **point of the hock**. The small bones of the hock are interposed between the astragalus and os calcis, and the cannon-bone and the two splint bones. The **fibula** is a rudimentary bone, which is attached to the tibia, and which corresponds to the ulna. According to Chauveau, the patella has no analogue in the fore extremity. The bones below the hock are similar to those below the knee.

**Analogies between the bones of man and the horse.**—The horse possesses no collar bone, consequently there is no bony connection between his fore
extremity and trunk. The humerus, elbow and fore arm are the same in both, except that the ulna is, comparatively, far more developed in man than in the horse. The knee of the latter corresponds to the wrist of the former. The five bones between the wrist and the first row of knuckles are represented by the cannon and splint bones; two of these bones having disappeared in the evolution of the horse (Chap. XXIX.). The fetlock is analogous to the first row of knuckles of our hand. The long pastern bone corresponds to the first row of bones of the fingers; the short one, to the second row; the coffin bone, to the third row; and the hoof, to our nails. The navicular bone is a detached bone which has no counterpart in our frame. In the hind limb, the stifle represents our knee; the tibia, the shin; the hock, the ankle; the point of the hock, the heel; and so on. In man, the fibula is a fully developed bone. We may thus see that the horse is an animal which moves on the tips of his fingers and toes (unguligrade); and that he has only one toe (or finger) to each leg.

**Joints and Ligaments.**—Joints may be divided into those which admit of more or less motion, and those which are immovable. The ends of the bones which form them are, in both cases, held together by strong inelastic ligaments, of which there are various kinds. Capsular ligaments, for instance, loosely encircle their joints in order to protect the apparatus which lubricates the ends of the bones. Lateral ligaments are placed on each side of the joint, and, being attached both above and below it, keep the bones together, while admitting often of considerable play. Annular ligaments form protecting sheaths for the passage of tendons; and interosseous ligaments bind bones closely together. Besides these, we have suspensory and check ligaments, which, as far as we are at present concerned, are respectively represented by the structures, bearing these names, which are found in the legs, below the knees and hocks.

The ligaments to which I have referred are, like tendons, composed of white fibrous tissue (a variety of connective tissue, see p. 12), which is hard, strong, and inelastic. Yellow ligaments are, without going into minute differences, to be distinguished by the fact of their yellow colour, and by the possession of considerable elasticity, which enables them to passively bear weights which would otherwise fall on the muscles. A familiar instance of the manner in which elastic ligaments mechanically save the expenditure of muscular force, is afforded by the arrangement which keeps the claws of a cat retracted without entailing exertion on the animal; for each claw is kept back by a small elastic ligament, which becomes stretched when the digits of the paw are extended by their muscles. As soon as these muscles cease to act, the ligaments, by their power of contraction, regain their natural length and retract the claws. An enormously powerful elastic ligament is attached to the withers, and goes straight from them, in the form of a cord, to the top of the head (the bony prominence between the ears), to which it is inserted. At about a third of the distance from the head to the withers, a broad sheet of elastic tissue is given off from the corded portion,
and is united to all the spines of the neck vertebrae, except the first. This sheet accordingly acts as a partition between the muscles on the respective sides of the upper part of the neck. The entire ligament, therefore, by its strength and elasticity greatly aids the muscles in supporting the weight of the head and neck. The amount of stretching which it can undergo in ordinary circumstances may be approximately estimated by comparing the length of the neck, when the head is held up in its usual position, to that when it is lowered to allow the animal to feed off the ground. In the first case, with a horse 15.3 high, it will probably not exceed 28 inches in length; but in the latter it must be over a yard long, supposing that the animal does not unduly bend his knees. Any depression or elevation beyond the position occupied by the head when the horse is asleep standing, has to be obtained by muscular force. This ligament is popularly called the \textit{jackwax}. Without being pedantic, we might, I think, more appropriately term it the \textit{suspensory ligament of the head and neck}. I may add that it is continuous with the strong, white fibrous ligament which commences on the spine of the sacrum and runs along the top of the spines of the vertebrae of the loins and back, binding them together, until it nearly reaches the summit of the withers, where its fibres assume the character of yellow elastic tissue. On the top of this large ligament there is a layer of fat, which in entire horses (especially if they be coarsely bred) often increases to a great size, and consequently gives them a high and thick crest (Fig. 263). The intestines of the horse are supported by the \textit{abdominal tunic}, which covers the muscles of the lower part of the belly, and consists of a broad, strong sheet of yellow elastic tissue. It acts like an elastic abdominal belt.

There is considerable power of movement between the head and the first vertebra of the neck (the \textit{atlas}), and between the different \textit{neck vertebrae} themselves; but hardly any between the \textit{dorsal vertebrae}. The \textit{loin vertebrae} can be flexed and extended to a slight degree on each other; but are capable of only very little motion from side to side. The \textit{sacrum}, as before mentioned, forms in the adult horse a single bone, on which the pelvis rests, and with which it is connected by powerful ligaments that greatly restrict its movements on the spine. We have also seen that the thigh bones articulate with the pelvis. The bones of the \textit{tail} possess considerable mobility. The solid connection thus afforded to the hind limbs, with the trunk, enables the former to transmit to the latter the forward impetus given during progression with the least possible loss of power. The capability of the loins to be flexed and extended is necessary in order to facilitate the action of the loin muscles, which are important agents in locomotion (p. 52). The mobility of the head, neck, and, to a much lesser degree, of the tail, acting as they do as balancing poles, is extremely useful in enabling the animal to perform with ease and precision many of the varied and difficult movements demanded of him. We may see that any power of lateral motion which the trunk (not counting the head, neck and tail) may possess, however much it may make the horse quick and "handy" at turning, will militate against his speed in a forward direction.
The respective ends of the first eight ribs form movable joints with the spine and breast bone; the first articulating with the last neck vertebra and first dorsal vertebra; the second with the first and second dorsal vertebrae, and so on. They are rigidly connected to their cartilages, of which those of the first eight, or true, ribs form movable joints with the breast bone. Commencing from the spine, "the ribs pass outwards and backwards, and then in an arched direction downwards, their cartilages inclining inwards and forwards" (Strangeways). Owing to the peculiar manner in which the ribs are curved, and to the fact that the ends of the true ribs can pivot round in the joints which they form with the spine and breast bone, while the false ribs also form movable joints with the spine; the capacity of the chest is capable of becoming much enlarged when the middle portion of the ribs are pulled forward by muscles that are attached to them. The mobility of the ribs, which is all but absent in the first one, gradually increases as they go backwards. They also increase in rotundity in the same manner, the first one being the flattest. The first rib is the shortest, and each succeeding one is longer than the one next in front of it, till the eighth or ninth rib, the ribs behind which gradually decrease in length up to the last one, which is nearly as short as the first rib. Owing to the direct connection which the first eight ribs have with the breast bone, their power of movement and, consequently, their action in increasing the capacity of the chest is less than that of the false ribs. Hence, when seeking for signs of good breathing power in a horse, we should attach far more importance to rotundity of the rear portion of the chest than of the front part. As a practical guide I might say that the former region might, in the saddled horse, be regarded roughly as the portion of the ribs behind the saddle flaps, and the latter as that covered by them. "It can be proved by observation, that the middle false ribs are those which have the greatest power of being drawn forwards and outwards. The ribs behind them successively lose more and more their power of displacement up to the last one, the lower end of which can be raised and lowered a little, without appreciably altering its distance from the point of the hip" (Colin).

The fore limb is connected to the trunk by muscles, to which I shall allude on page 31.

The shoulder joint is a ball and socket articulation, which possesses considerable power of motion.

The elbow is a hinge joint, which can be bent and extended.

In the knee we have three hinge joints, of which that between the radius and first row of bones is capable of a large amount of motion; that between the two rows of much less; while that between the second row and cannon-bones possesses hardly any power of movement.

The bones at the back of the knee are united together by an extremely strong ligament, one of the bands of which closes up the gap left between the point of the trapezium and the inside of the knee, so as to form a channel for the "back tendons" to pass through.

The sesamoid bones are fixed immovably to the back of the fetlock joint.
The *fetlock*, *pastern*, and *coffin* joints are hinge joints, which possess
more or less play.

The *hind limb is connected to the trunk*, as we have already seen, by
the pelvis.

The *hip joint*, formed by the head of the thigh bone and cavity in the
pelvis, is a ball and socket joint.

In the *stifle* we find two articulations—one with the thigh bone and tibia,
the other with the thigh bone and patella, which is firmly attached to the
tibia by ligaments in order to enable it to resist the action of those muscles
of the thigh which are inserted on it.

The *true hock joint* is formed by the tibia and astragalus. It is a
hinge joint, which, owing to the oblique manner in which its grooves are
placed, causes the foot to be turned slightly outward when the joint is
either flexed or extended. The other joints of the hock possess hardly
any power of movement.

The *astragalus, os calcis, small bones of the hock, hind cannon, and splint
bones* are firmly connected together by ligaments.

The *joints below the hock* are similar to those below the knee.

**Muscles.**—I shall now consider, in the briefest possible manner, the
principal muscles which are used in locomotion.

A broad sheet of muscle (the *panniculus*) lies immediately underneath
the skin that covers the neck, sides of the chest, and abdomen. In thin
horses, its rear border is usually defined by an irregular line (p. 229)
which runs along the side downwards and backwards towards the
groin. This muscle is attached, round its borders, to the skin and
superficial muscles by sheets of fibrous tissue. By quickly contracting and
relaxing alternately, it causes the skin to twitch, and thus gets rid of flies, etc.,
that may have alighted on the surface underneath which a portion of this
muscle lies. It is principally found on those parts which the horse has
difficulty in reaching with his lips, tail, or mane. As the process of training
for racing purposes appears to largely develop this muscle, I cannot help
thinking that it aids in forced expiration—expelling the air from the lungs—
during the quickened breathing entailed by fast work; although anatomists
do not ascribe such action to it.

The *neck, back, and loins are flexed* by muscles which lie immediately
underneath the spine. The *head is bent* by muscles that proceed—one on
each side—from the breast bone to the lower jaw, and by others which
connect the neck and head together. The *head is extended* by muscles that
are attached to the poll and bones of the neck and by others that proceed
from the poll to the withers. The *neck is extended* by the last mentioned
muscles, and by those which connect the spine of one vertebra with the
body of the one in front of it. The *back and loins are extended* by muscles
which are similar in action to the one just alluded to, and by the *longissimus
dorsi*, which is the most powerful muscle of the body, and is the chief
extensor of the spine. It forms the principal portion of the fleshy mass
which lies over the loins and back. It is attached to the pelvis, sacrum, all
the loin and dorsal vertebrae, the last four bones of the neck, and to the
ribs. As the spines of the vertebrae (including the withers) form a part of its
attachments, it follows that the more they are developed, the more powerful
will be the extension of the loins and back.

Muscles which connect the fore limb to the body.—The shoulder blade is
connected to the trunk principally by a very strong, fan-shaped muscle,
which is attached at its middle to the inside of the shoulder blade. Its
front end is connected to the last five bones of the neck; and its other end
to the first eight ribs. When the front portion contracts, the shoulder blade
is drawn forward; when the rear portion contracts, this bone is pulled back.
This muscle, from the manner of its attachment, acts as a sling for the fore
limb. The upper part of the shoulder blade is connected to the trunk, from its
inner extremity by a muscle which has one end attached to the suspensory
ligament of the head and neck, and the other to the withers. Hence, on
contracting, it draws the shoulder blade forwards and upwards. The outside
of the shoulder blade is connected to the trunk, at about its upper third, by a
muscle which has one branch going to the withers, and the other to the
supensory ligament of the head and neck. It can thus raise the shoulder
blade, or work it backwards or forwards. The fore limb is drawn forward
chiefly, however, by the action of a muscle which is attached, at one end, to
the top of the head and first four neck vertebrae, and by the other to the
middle of the humerus. We may see from the foregoing remarks, that
length of neck and height of withers are favourable conditions for the firm
attachment of the shoulder blade to the trunk and for the free action of the
shoulder.

The fore limb is connected to the breast bone by a muscle which is attached
to the breast bone and humerus.

The fore limb is drawn back, principally, by two muscles, one of which is
attached, at one end, to the abdominal tunic (see p. 28) and breast bone;
and at the other, to the humerus and shoulder blade, close to the shoulder
joint. The other muscle (the latissimus dorsi) has its origin on the vertebrae
of the loins and back, and is inserted on the humerus, which it consequently
draws backwards and upwards when it contracts. The first mentioned
muscle tends to draw it backwards and downwards.

Muscles of the fore limb.—When the fore leg is advanced, the shoulder
joint is extended and the elbow joint flexed. When it is drawn back, the
opposite to this takes place. Agreeably to these actions, we find a powerful
muscle attached, by one end, to the front part of the shoulder blade, just
above the joint; and by the other end to the front of the radius immediately
below the elbow joint, so that, when it contracts, it extends the shoulder and
flexes the elbow. Another muscle, being attached to the rearmost corner of
the shoulder blade and to the point of the elbow, flexes the shoulder and
extends the elbow. Besides these muscles, there are various others which
respectively aid in the flexion and extension of these joints. The chief
muscle that extends the knee has its origin on the front part of the humerus,
just above the elbow joint, and running down the fore arm, is joined to its
tendon, which passes over the knee, and which is inserted on the head of the
cannon-bone. The three muscles which bend the knee take their origin on
the back part of the humerus, just above the elbow joint, and are inserted on
the trapezium and splint bones. The two muscles which extend the fetlock,
pastern and coffin joints, run down the front of the fore arm. One of them has
its origin at the head of the radius, and is inserted on the front part of the
long pastern bone. The other commences on the humerus, just above
the elbow joint, and ends on the front and upper part of the coffin bone.

*The muscles which flex the fetlock, pastern, and coffin joints (the flexor muscles of
the foot)* and aid in bending the knee, take their origin on the back part of
the humerus, just above the elbow joint, and proceed down the back of the
fore arm. A little above the knee they are joined to their tendons (the back
tendons), which pass through the sheath formed by the trapezium and the
annular ligament at the back of the knee. From the face they run down the
back of the cannon bone. The front one, which lies next the suspensory
ligament, goes over the sesamoid bones, which form a pulley for it; down
the back of the pastern; over the navicular bone, which also acts as a
pulley; and is finally inserted on the base of the coffin-bone. The rearmost
tendon, which lies between the front one and the skin, forms a sheath for
its fellow at the back of the fetlock, and, dividing in two, is inserted on
the short pastern bone. There are two short muscles which assist the front
one of these two muscles, but which I need not further allude to. As the
action of the suspensory and check ligament is closely connected with that
of the flexor muscles of the foot, I may appropriately describe them here.

The *suspensory ligament* lies at the back of the cannon-bone and between the
two splint bones. It has its origin at the head of the cannon-bone and lower
row of the small bones of the knee. At about two-thirds of the distance
from the knee to the fetlock, it divides into two branches, which are
respectively inserted on the summits of the sesamoid bones. They then
extend downwards and forwards, and unite together, at the front and about
the middle of the pastern, with the tendon of the muscle which extends
the foot. The suspensory ligament is composed of white fibrous tissue, with
a few muscular fibres in it, and acts in supporting the fetlock. It is
generally considered to be inelastic, although Goubaux and Barrier
entertain the opposite opinion. They remark that "its obscurely muscular
structure, and the manner in which its fibres inter-cross, render it a true
elastic brace, which counteracts the effects of weight, as long as they do not
overcome the resistance and strength of the tissues." In omnivorous
and carnivorous animals this ligament is replaced by a muscle which
has similar functions. The *check ligament* has nearly the same origin
as the suspensory ligament and joins the front back tendon, at a point
about half-way down the cannon-bone. Its office is to aid in supporting
the fetlock and to relieve the muscles of the tendon, with which it is con-
ected, of weight.

*Muscles of the hind limb.*—The hip is extended by the great croup
muscle, and also by some of the muscles which lie at the back of the thigh bone. One end of the great croup muscle is attached to the upper surface of the front portion of the pelvis, and, proceeding along the side of the sacrum, reaches as far as the last rib. The other end is inserted to the summit of the portion of the thigh bone which projects above the hip joint. The muscles at the back of the thigh bone have their origin, chiefly, on the under surface of the pelvis, from behind the hip joint to the point of the buttock; and are inserted principally to the lower part of the thigh bone or to the upper portion of the tibia.

The hip is flexed by muscles that have their origin on the under surface of the lon vertebre, and are inserted on the thigh bone; and also by muscles which are attached to the under surface of the pelvis in front of the hip joint, and to the thigh bone, patella, or tibia.

The stifle is extended by one muscle which has its origin on the under surface of the pelvis, just in front of the hip joint, and is inserted on the patella, and by two others which are attached to the upper part of the thigh bone and to the patella. The first mentioned muscle flexes the hip at the same time that it extends the stifle.

The stifle is flexed chiefly by a muscle which is attached to the portion of the pelvis behind the hip joint, and to the tibia.

The hock is extended, for the most part, by muscles which form the rear-most portion of the gaskin ("second thigh"). They have their origin on the lower end of the thigh bone, and are inserted to the point of the hock by their tendons, which lie one over the other, and constitute the tendo Achillis. The underneath tendon terminates at the point of the hock; but the other is continued down the back of the leg as the rearmost one of the two back tendons, and is inserted on the short pastern bone, as in the fore limb. Owing to the double insertion of this tendon, the hock cannot be extended without the fetlock being flexed at the same time; hence the success of the expedient, for the prevention of kicking, of securely fixing in the hollow of the pastern some hard object of suitable shape, so as to prevent the joint between the two pastern bones from becoming flexed.

The joints below the hock are extended by muscles which take their origin near the stifle joint, run down the front of the hind leg, are continued as tendons down the front of the cannon-bone, and are inserted on the bones of the pastern, and to the front and highest point of the coffin bone.

The joints below the hock are flexed by a muscle of the gaskin, which muscle originates at the back of the upper portion of the tibia, behind which it runs down to a little above the hock joint, when it is continued as a tendon that passes over the groove formed on the os calcis. It then proceeds down the back of the cannon-bone, as the front one of the two back tendons, and terminates in the same manner as in the fore limb. The muscle of the rear back tendon, as we have already seen, also aids in flexing the fetlock and pastern joints.
Heart and Lungs.—The heart is a hollow muscle which acts as a force pump in sending the blood through the arteries to the various parts of the body. The arteries commence on the left side of the heart, by one large trunk, which splits up, as it goes on, into an innumerable number of small branches, that, as a rule, terminate in a microscopic network of minute canals called capillaries. These canals, which probably do not exceed a fortieth of an inch in length, gradually enlarge on the side away from the arteries, and open out into small veins, which, uniting with each other as they approach the heart, enter its right side by two large branches and a few small ones. The heart now forces this venous blood through the pulmonary artery to the lungs, which return it by a system of capillaries and veins to the heart. We must remember that the network of capillaries runs through every tissue which contains blood. Thus, for instance, the blood which goes to the foot of the horse, and that which proceeds to the substance of the heart itself, flow to their respective parts through certain arteries, pass through a very short network of capillaries, and return to the heart by the veins; a long circuit being made in the first case; a short one, in the second.

The necessary amount of nutritive matter and water is taken up from the food and drink contained in the stomach and intestines by small vessels which carry it into the veins, and is thus finally brought into the capillaries, the walls of which are so thin that it exudes through them, and in this manner nourishes the various tissues. I may mention that, before food can be taken up by the system, it is necessary that it should be thoroughly dissolved. As the tissues are being constantly broken up as well as repaired, the capillaries also serve to take up the waste matters and carry them into the veins. When this impure or venous blood is pumped by the right side of the heart into the lungs, it is acted upon, there, by the oxygen of the air that is taken into the chest at each breath, and is returned from the lungs to the left side of the heart in a comparatively high state of purity. When the blood leaves the lungs, it carries with it a certain amount of oxygen, which, uniting with the broken-up material in the various tissues, converts it into products which can be readily removed. I need not dwell longer on this subject; for it is fully explained in every elementary book on physiology, as, for instance, that by Huxley.

In order that a muscle may work—i.e., contract on being stimulated by its nerves—it is necessary that it should be supplied with oxygen. Also, the severer the labour, the more oxygen is used up in the muscles and the larger is the supply required. As the blood has a shorter distance to travel in order to make a complete circuit in the blood vessels of a small animal, than in that of a large one of the same kind; we might infer that the blood of the former passes more frequently during a given space of time through the lungs, than that of the latter. The truth of this supposition is fully borne out in practice; for we may observe, on an average, that the pulse of a heavy cart-horse beats about thirty-five times a minute; that of a small pony, about forty-five times. Hence we find that, speaking generally, small horses
NERVOUS SYSTEM OF THE HORSE.

can “stay” better than large ones; for the power of “staying” is dependent on the capability, possessed by muscles, of retaining for a long time their contractile power. Also, they recover quicker than big horses from the effects of severe work, owing to the fact that repair of worn-out tissue and removal of waste matters from the system is carried on at a faster rate. In fact, they possess more “vitality.” Again, the larger the lungs—other things being equal—the greater will be the amount of oxygen taken into the blood, and of impurities given off from the blood into the air.

Nervous System of the Horse.—The nervous system of the horse is the power which stimulates and directs the action of his muscles in locomotion, and is the source of his mental capacity. We may regard it as divided into nerve centres and conducting nerves. To employ a well-worn simile, we may look upon a nerve centre as a telegraph station to which and from which messages are sent and despatched. The nerves (the sensory nerves) by which the horse sees, feels, hears, smells, and tastes, conduct the impressions they receive to some nerve centre, which may do one of three things. (1) It may, in response to the message received, send, on its own authority, by another line of nerves (the motor nerves), an order (or stimulus) to certain muscles to move. Such a movement will be by reflex action—that is, the impulse will be immediately reflected back. (2) Instead of acting on its own account, it may merely transmit the message on to another and more important nerve centre to decide what answer will be given. (3) It may use a portion of its transmitting power in reflex action, and a part of it in reporting the matter to head-quarters.

Besides the power which nerve centres have of exciting the muscles to move in response to a stimulus received from the sensory nerves, they can, by their own initiative, make their motor nerves stimulate to movement the muscles which are supplied with these particular motor nerves.

The chief nerve centres that are connected with the muscles of locomotion, are grouped together in a long column which fills the brain cavity, and spinal canal, and may be divided into the brain and spinal cord.

The spinal cord, though it is formed of a number of nerve centres, is the chief conducting medium by which impressions received by the senses are conveyed to the brain, and is the means by which orders from the brain are transmitted to the muscles of the limbs.

We may divide the brain into the medulla oblongata, the cerebellum, and the cerebrum.

The medulla oblongata connects the other two portions of the brain with the spinal cord. It is the nervous centre of the function of breathing. Animals, for purposes of experiment, have had their spinal cord, and the whole of their brain, except the medulla, removed, and yet they have continued to breathe and live. But were the medulla injured, death from inability to breathe would at once ensue.

The cerebellum appears to be the organ of muscular sense and of combined muscular effort. By its muscular sense the animal can tell, from experience,
the amount of muscular force required in performing its various voluntary movements. We cannot, by an effort of will, move any one particular muscle of our body; but we can cause our limbs to perform definite movements which will require the combined action of various muscles, and which are under the control of the cerebellum.

The cerebrum is the organ of intellect, thought, and will. "Removal of the cerebrum in the lower animals appears to reduce them to a condition of a mechanism without spontaneity. A pigeon from which the cerebrum has been removed will remain motionless and apparently unconscious unless disturbed. When disturbed in any way, it soon recovers its former position. When thrown into the air it flies" (Kirke's Physiology). The cerebrum appears to be the organ in which a conclusion or thought is formed from a message or number of messages proceeding from the senses. If, for instance, a man standing near a horse's hind-quarters touches him with a stick, and if the animal kicks the stick, he will perform, more or less, a reflex action. If, however, the horse recognises who the real offending party is, and kicks the man, he will have drawn a conclusion from the message received from his sense of feeling and of sight, and will have acted on such conclusion, which would be, more or less, an effort of reason.

Among the intellectual faculties, of which the cerebrum is the special organ, we have, prominently, reason and memory. Although the horse is greatly deficient in the former, which is by far the higher faculty of the two, he possesses the latter in special excellence.

The cerebrum is placed immediately underneath the forehead, at the centre of which it is covered by only a thin plate of bone. The cerebellum, which, in the horse, is a great deal smaller than the cerebrum, lies below the (occipital crest) top of the head, when the face is held at an angle of about 45° with the ground.

The proportion which the weight of the brain bears to that of the spinal cord, is regarded by many as a fair guide to the intellectual capacity of an animal. The following is a list of a few examples of the average number of times the brain is heavier than the spinal cord in certain animals:—

<table>

The order of intellectual capacity given in the above table agrees fairly well with the conclusions drawn from experience.
CHAPTER V.
MECHANISM OF BREATHING.

The body of the horse (Fig. 13), viewed apart from his head, neck, limbs, and tail, may be divided into chest and abdomen (belly), the former containing the lungs and heart; the latter, the stomach, intestines, liver, bladder, and other vital organs. This division is effected by a broad and somewhat bell-shaped muscle, the diaphragm or midriff, which is attached, round its margin, to the ends
of the last twelve ribs, to the rearmost extremity of the breast-bone, and to the spine under the loins, while its apex or centre projects forwards. When it contracts, it tends to become flat, and thus enlarges the capacity of the chest by pushing back the contents of the abdomen. Its action, especially during forced breathing, is aided by that of another muscle, which is attached by one end to the last four neck vertebrae, and by the other to the first rib, which it pulls forward on contracting, and in this manner helps to increase the size of the chest.

Air is taken into, and expelled from, the lungs by means of the alternate increase and diminution of the capacity of the chest. When the former act occurs, the air contained in the lungs becomes rarefied, and consequently the external air rushes in through the animal's nostrils to restore the balance of pressure. When the latter takes place, a portion of the air which is already in the lungs is forced out. It is evident, therefore, that the power of taking a large volume of air into the lungs at each breath, is more dependent on the difference between the respective capacities of the chest when expanded, and contracted, than on the actual size of the chest itself.

The act of breathing is called respiration; that of expelling air from the lungs, expiration; and that of drawing it in, inspiration.

The chest is enlarged by the diaphragm, as we have seen; and also by muscles which pull the middle pieces of the ribs forward, so as to make the cavity wider from side to side, and consequently to increase its size. The ribs are drawn forward by muscles which cover them, and by others which are situated between the successive pairs of ribs. The lower ends of some of the ribs are also drawn up during the act of inspiration. On page 29, I have remarked on the power the ribs have of pivoting on their ends. I may point out that when the air which is within the chest, becomes rarefied at the commencement of the act of inspiration, the lungs themselves passively
dilate, and thus allow the incoming air to gain ready access to the bronchial tubes and air-cells.

When the animal is at rest, the elastic recoil of the ribs and lungs is sufficient to expel the *tidal air*, as the amount changed at each breath is called. The volume of air which remains in the lungs after expiration, greatly exceeds—perhaps five or six times—that of the tidal air.

In forced breathing, as during active movement, several muscles which are not employed for tranquil respiration are called into play, particularly those used in forced expiration, as we may see by the heaving flanks of an animal which is "blown." The muscles that cover the ribs and belly, aid in forced expiration by compressing these parts, and thereby causing the walls of the chest to "fall in," and the contents of the abdomen to project forward into that cavity. Quick work naturally develops the muscles of forced respiration.

I may point out that the muscles of the flank (known to anatomists as the great and small oblique, and the transverse) aid in respiration. Consequently, when they are well developed, the flank is not so hollow as it would be if they were wanting in size.

I may mention that no hard and fast line can be drawn between tranquil and forced breathing, although the broad differences between them are clearly marked.

In order that the horse may have his breathing power fully developed, it is necessary that the capacity of the chest at the end of an act of expiration should differ as much as possible from what it will be at the termination of the act of inspiration. For this reason the chest should be deep, the ribs well arched, and, at the same time, they should have a good inclination to the rear. The back ribs should be long, so as to augment the size of the chest; and the muscles which move the ribs, as well as the muscles of the belly, should be largely developed. I shall further allude, in Chapter XVII., to the shape of the chest and ribs.
CHAPTER VI.

DISTRIBUTION OF WEIGHT IN THE HORSE'S BODY.

Comparative Weight borne by the Fore and Hind Limbs—Centre of Gravity.

Comparative Weight borne by the Fore and Hind Limbs.—General Morris, of the French Army, appears to have been the first to make experiments as to the distribution of weight between the fore and hind limbs of the horse. He found that, taking one animal with another, it is as five is to four; and that the fact of the neck being long, as in the thoroughbred, causes more weight to be thrown on the fore hand, than when that part is short and massive, as in the heavy cart-horse. The proportion which he obtained from an average of eleven horses that had light heads and necks—the latter being presumably long—was as four is to three. Colin puts the average at fully three to two. Goubaux and Barrier have proved by a number of careful trials, that the lower the withers are, as compared to the croup, the greater is the proportion of weight supported by the fore limbs; and vice versa. This is agreeable to what we might have inferred from the manner in which the horse raises his croup to kick, or his withers to rear. As the hind half of the trunk is, in all classes, heavier than the fore half, it follows that the extra weight in front is mainly due to the fact of the head and neck being in advance of the fore legs. The longer the body, and the heavier the belly, the more will this distribution of weight be equalised.

Centre of Gravity.—The centre of gravity of a body is an imaginary point in that body, so placed that if the body be supported immediately underneath the centre of gravity, it will be in equilibrium (or rest). Consequently, if a body be balanced at a point on its surface, a perpendicular line drawn from that point will pass through the centre of gravity; and the intersection of two or more such lines will determine the position of the centre of gravity. If the body be of uniform density, the position of the centre of gravity will be the same as that of the centre of the figure; but if it be heavier at one side than at the other, the centre of gravity will be nearer the former than the latter. For instance, in ships, with the view of obtaining increased security from an upset, the centre of gravity is placed below the centre of the hull. If, for example, we want to ascertain the position of the centre of gravity of a loaded club, we may take one line through its axis, and another across it, at the point where it balances, when
placed horizontally. The lower the centre of gravity of a body, the more stable will be its equilibrium, as we may see by experimenting with a loaded stick of uniform thickness; firstly, balanced on its light end, and, secondly, on its heavy extremity.

In the living animal, the position of the centre of gravity is constantly changing; on account of the manner in which the respective positions of the various parts alter, especially during movements of the head and neck.

Colin, the well-known author of *Physiologie Comparée des Animaux Domestiques*, remarks that "the centre of gravity, the exact position of which has never been determined, nearly corresponds, in the horse, to the intersection of two lines—one, vertical, falling behind the xiphoid appendage [cartilage at rearmost point of the breast bone] of the sternum; the other, horizontal, dividing the middle third from the lower third of the body." Fig. 14, which I have taken from Goubaux and Barrier's *L'Extérieur du Cheval*, is drawn in conformity with Colin's remarks. The point of intersection of the two dotted lines in this figure, shows the position of the supposed centre of gravity.

We may readily see that the less deep is a horse's body, compared to his length of leg—in other words, the more "daylight" he has under him—the higher and more unstable will be his centre of gravity; and *vice versa*. Taking the foregoing remarks with those on the effect which instability of equilibrium has on speed (p. 54), we may conclude that the faster the horse, other things being equal, the greater will be the proportion of weight on his fore hand.
Definition.—A lever is a rigid bar which has a fulcrum, or fixed point, so arranged that movement can be communicated to a weight at another point on it, by a power acting on a third point on the bar. Agreeably to the relative positions of the fulcrum (F), weight (W), and power (P), we have the three following orders of levers.

First Order.—P.F.W. (Fig. 15), as when two persons make a see-saw by sitting on the opposite ends of a plank which rests on some convenient fulcrum. We have this order of lever in the bones from the point of the hock to the foot, when a horse kicks out with a hind leg (Fig. 39).

Second Order.—P.W.F. (Fig. 16). A wheel-barrow, when lifted in the usual manner, furnishes us with an instance of this lever; the ground on which the wheel rests being the fulcrum; the barrow, the weight; and the arms of the person who lifts the handles, the force. We have another example in an oar employed to row a boat; the water being the unstable fulcrum, and the rowlock being the point through which the weight (the boat) is pushed forward. The bones and muscles which I have taken to illustrate
the first order of lever will serve our turn here, if we imagine the power to be exerted in propelling the body to the front, through the tibia (the bone that is situated between the hock and stifle), while the toe rests on the fulcrum formed by the ground (Fig. 40).

Third Order.—W.P.F. (Fig. 17). This form of lever occurs in a fishing rod, with which a man tries to lift a heavy trout out of the water. The weight is at the point of the rod; the fulcrum, at the butt, is formed by one hand; and the power is supplied by the other hand, a little above the butt. We have this lever in the bones below the hock, when the horse bends that joint by lifting his foot off the ground (Fig. 41). Here, the power is derived from the muscle which is placed in front of the tibia; the weight is that of the limb below the hock; and the fulcrum is formed by the tibia. I may remark in passing that the os calcis does not come into this lever, except in counterbalancing, to some slight extent, the weight of the leg below the hock.

Relations between the Power and Weight in Levers.—The farther the power is from the fulcrum, the greater will be the mechanical advantage at which it will act; and vice versa. Thus, if one arm of a see-saw is longer than the other, a comparatively light weight at the end of the former will counterbalance a heavy one at the extremity of the latter. Also, the longer an oar is “in-board,” as in an outrigger, the greater will be the power which a rower will have. If we apply this principle to the horse, we shall see that the longer is the os calcis (Figs. 39 and 40), the greater will be the mechanical advantage at which the muscles of the gaskin will act in kicking or propelling the body forward. As length of os
calais gives increased leverage in the hind limb, so does length of trapeziun afford it in the fore leg.

If we wish to express these relations mathematically, we have the following proportions for the three orders of levers:—

\[ \frac{P}{W} = \frac{wF}{\rho F} \]

Here, \( wF \) is the distance of the point of application of the weight from the fulcrum; and \( \rho F \), the distance of the power from the fulcrum.

Comparisons between Power and Weight in Muscular Levers.—We may observe that the power always acts at a mechanical disadvantage in levers of the third order. As the majority of the levers which are used in animal locomotion, act at a mechanical disadvantage; I shall now investigate the cause of this apparent anomaly. I may first remark that the measure of work done by a force is found by multiplying the weight by the distance through which it has been moved. Thus, suppose two men are engaged in raising weights, one having a single block pulley to lift a weight of 25 lbs., while the other, to raise 100 lbs., uses a multiplying block which increases the power fourfold; the former will raise his 25 lbs. 4 ft. off the ground in the same time and with the same expenditure of force as the latter will lift his 100 lbs. to a height of 1 ft. In fact, what is gained in power is lost in distance. This law holds equally good with levers, as we may see from the fact, for instance, that a small amount of contraction of the muscle which bends the hock, causes the hind foot to move through a considerable space. Were the hock bent, for example, by a muscle that had its two points of attachment at the stiffe and fetlock (instead, as is actually the case, at the stiffe and a little below the hock), such muscle would act at far greater mechanical advantage than the present flexor of the hock; but it could not bend that joint to anything like the same extent, because muscles cannot contract to more than about two-thirds of their normal length. Besides, such an arrangement would be extremely inconvenient for every-day work, and would increase the liability of the limb to injury. Although there is, therefore, a very large expenditure of muscular force in the action of the levers of the limbs; there is an equally large gain in flexion and extension, and consequently in speed. Their arrangement, also, enables the body to be made of a compact form, and to be suited to its surroundings.

Directions in which the Power and Weight respectively Act.—In the theoretical levers which I have given (Figs. 15, 16, and 17), I have assumed that the power and weight acted at right angles to the lever, and that they were consequently parallel to each other. In the actual levers (those of the hock) which I have taken into consideration, we may see that this is not the case. I may mention that the nearer a force is to being at right angles with its lever, the greater is the mechanical advantage at which
it will work. If, in a lever of the first order, for instance, we have the power and weight, as in Fig. 18, acting in directions which are not parallel to each other, such forces (if the lever be in equilibrium) will then be inversely proportionate to the length of the perpendiculars drawn from the fulcrum, to their respective directions. Thus in Fig. 18 we have \( P : W : F : F' \). We therefore see that \( W \), which is nearly at right angles to \( a \dot{b} \), acts much more advantageously than \( P \), which is in a much more oblique direction to it. This would be equally true in the other two kinds of levers. I need not stop to prove the foregoing well-known mechanical law; as its solution can be found in any book on elementary statics.

Acting on the principle just enunciated, the cart-horse, with the view of obtaining the utmost mechanical advantage, when trying to draw a heavy load, will naturally endeavour to move the levers of his limbs (when straightening them out) with the power, as nearly as possible, at right angles to each respective lever. Hence he will obtain his results by only slight bending of the joints, and consequently his steps will be short. We may see this action of the levers of the hind limbs well shown by the manner in which he will crouch down behind when he makes a strong effort with his hind legs while exerting the fore legs but little, as may occur when the roadway is slippery. The galloper, on the contrary, will require the power of straightening out his limbs to their utmost extent (p. 51), and will thus obtain speed at a lavish expenditure of muscular effort. This is especially well shown in the action of the fetlock joint (Fig. 38); for if the pastern be long and sloping, the mechanical disadvantage will be great, but the gain in speed will be equally large. If the pastern be upright, the fetlock will work advantageously as far as the weight to be moved is concerned; but it will contribute little to the attainment of speed.

---

**Fig. 18.—Lever of First Order with Directions of Power and Weight Oblique to Each Other.**
CHAPTER VIII.

MECHANISM OF EQUINE LOCOMOTION.

Displacement of the Centre of Gravity—Manner in which Propulsion is effected by the Limbs—Direction of Propulsion, and Distance through which the Centre of Gravity of the Body is moved—Comparative Speed in the Action of the Limbs—Action of the Muscles which extend the Vertebrae—Width between each respective Pair of Legs as affecting Speed—Effect of Insecurity of Equilibrium on Speed—Fatigue from the various Paces—Action of the Head and Neck in Locomotion—Mechanism of the Fetlock Joint—Mechanism of the Hock Joint.

The remarks made under this heading should be taken in connection with those in the following five chapters. Some which are here given are necessary for the proper comprehension of the movements of the horse in his various paces; but others, in order that they may be understood, have been kept back, until the paces and draught have been discussed.

Displacement of the Centre of Gravity.—The actions which give rise to locomotion in the horse may be summed up as follows:—Advancement of a limb in order to bring a new base of support under the centre of gravity. Let us suppose that the man represented in Fig. 19 is standing with one foot advanced more than the other. His base of support (a b) will then be the area bounded by his feet and the lines joining them at each side. As long as the perpendicular (p) dropped from the centre of gravity falls within the base of support, the equilibrium of the body will be maintained. If the man, in this example, brings the centre of gravity of his body forward by straightening his left ankle joint, so that the perpendicular from the centre of gravity shall fall beyond the base of support (Fig. 20); it will be evident that in order to prevent the body from falling, he will have to bring the rear leg (which in this case is the left one) beyond the perpendicular dropped from the centre of gravity (Fig. 21). Precisely the same actions take place when the horse starts from the halt into the walk; for by the straightening of one or both hind legs, he brings the centre of gravity of his body beyond the toe of the most advanced fore foot, with the result that the other fore leg has to be carried forward in order to restore the equilibrium. In doing this, the first foot to quit the ground will usually
PROPULSION BY THE LIMBS.

be a fore one. I may remark that a succession of these displacements and recoveries will constitute the walk, run, or other pace. The same movements occur when leaping, except when the spring is made vertically upwards from a state of rest, in which case the centre of gravity is not displaced beyond the base of support.

Manner in which Propulsion is Effected by the Limbs.—The displacement of the centre of gravity, in the propulsion of the body, is accomplished by the straightening out of the limb or limbs, as the case may be. We can readily see how this gives the required impetus, if we consider the manner in which the shove-off is done by an expert swimmer in a bath, when he comes to the end of it, and wishes to touch, turn, and strike off without loss of time. He, as we all know, will, as much as possible, draw up the leg with which he is going to give the shove off, and having applied it to the side of the bath (Fig. 22), will suddenly straighten it out, with the result that his body will be shot forward (Fig. 23). Here the drawn-up leg, which acts as a spring, is placed between two objects: one (the body) movable, the other (the side of the bath) immovable. When the leg is extended, the movable object is naturally the one to be displaced. Indentically the same action occurs in the various progressive movements of the horse. We may see it, also, in the run of the pedestrian, which is depicted in Figs. 24, 25 and 26; for the right leg, which is a good deal bent in Fig. 24, is nearly straight in Fig. 25. The straightening of the limb or limbs, in effecting the forward propulsion of the body, is even better shown in Figs. 27, 28, 29 and 30, which depict the standing leap.

I may mention that the propulsion of the hind limb of the horse takes place through the hip joint and pelvis. The impetus from the fore leg at the various paces may be regarded as through the elbow joint and humerus.

Fig. 29.
FORWARD PROPULSION OF MAN IN STANDING LEAP.
Direction of Propulsion and Distance through which the Centre of Gravity of the Body is Moved.—The direction of the propulsion given by a limb is necessarily through its column of bones. If we examine all the illustrations of the progressive movements of the horse, from Fig. 55 to Fig. 190, we shall see that in every case, just before a limb leaves the ground, it is directed backward and downward, as, for instance, the near hind in Fig. 105, and the off fore in Fig. 130. Hence the direction of propulsion in these cases must be forward and upward. The speed at which the body is moving will greatly influence the direction of the propulsion. Thus in Fig. 32, which is one of the series (Fig. 31 to Fig. 35) that shows the running high leap of a man, the impetus from the right leg is given vertically; yet the centre of gravity is projected forward at about an angle of 45° to the ground. The reason for this is, that in this case there are two forces of projection, namely, that derived from the extension of the right leg, and that due to the speed at which the pedestrian ran up to the jump before he “took off.” We have here the operation of
MECHANISM OF EQUINE LOCOMOTION.

"the parallelogram of forces." Thus, if the line $ab$ in Fig. 36 represents the horizontal force (derived from the speed) and $ac$ the vertical one (obtained from the right leg), and if we draw $ed$ parallel to $ab$, and $bd$ parallel to $ac$, we shall have the resultant force represented by the line $ad$, and the angle of elevation equal to the angle $dab$.

The upward motion given by the limb to the body is necessary to keep up the centre of gravity, which, if we wish the labour to be accomplished with a minimum amount of muscular effort, should be maintained as nearly as possible at one uniform height from the ground; for the distance through which the centre of gravity is moved will be a measure of the work done. Let us suppose at each step of a yard long by a horse, that the centre of gravity falls 4 inches, and that the animal has to go a distance of 1000 yards on a horizontal plane. It is evident that, in this case, the muscles of the horse's limbs would not alone have to carry the weight of the body 1000 yards, but would also have to raise it $33\frac{1}{3}$ feet $(1000 \times \frac{1}{3})$, which would be approximately equivalent to going over a hill that was $33\frac{1}{3}$ feet high and had a base 1000 yards broad. I need hardly say that the less the fall and rise at each step, the lower this suppositious hill would be, and, consequently, the easier it would be to walk over.

Although the duty of forward propulsion is chiefly performed by the hind limbs; the greater part of the work of adjusting the position of the centre of gravity during ordinary locomotion, falls on the fore limbs. When a horse, for instance, performs the high-school feat of cantering to the rear, the respective rôles would obviously be reversed. The question of the adjustment of the centre of gravity of the body, so that the muscles of locomotion may act to the best possible advantage, will be considered further on.

Comparative Speed in the Action of the Limbs.—The speed with which the body is projected forward, is directly proportionate to the speed with which the limb or limbs are straightened out, and has nothing to do with the strength of the muscles that move the parts. Hence, any excess of muscular development beyond that required for the due working of the limbs, will tend to diminish the speed by unnecessarily adding to the weight to be carried. For this reason, we never see great race-horses of the weight-carrying hunter build. Some of the best (St. Simon and Tim Whiffler, for
instance) have been slight horses. In fact, the son of Galopin and St. Angela (Figs. 9 and 229) had singularly light hind-quarters. Even Ormonde, who was very muscular for a race-horse, was anything but broad when viewed from behind.

The question of the speed of muscular contraction is an abstruse one which still remains unsettled. We know that if a muscle be stimulated by a shock of electricity, it will contract throughout its entire length at (practically) the same moment. Hence, under this condition, a long muscle would contract very nearly in the same time as a short one. When, however, a muscle is stimulated by the nerves which act in obedience to the will, the contraction of its various parts does not take place simultaneously, though at such a brief interval that we may regard the delay as unappreciable. Hence, in two limbs which resemble each other in every particular, except that one is short and the other long, the respective extension of both will be accomplished in very nearly the same time, and consequently the speed of the propulsion derived from the long leg will exceed that from the short one in nearly the proportion which their lengths bear to each other. This conclusion is in accordance with Marey’s statement (p. 4), that muscles of speed are long muscles. Besides this, physiology teaches us that the thicker muscles are, the slower, other things being equal, do they contract on becoming stimulated. We should content ourselves with taking a broad view of this subject; for conditions vary so much in individual cases, that it is not safe to dogmatise on it.

I need hardly say to those of my readers who have followed me so far, that the greater the ability to straighten the leg, the higher will be the speed of propulsion, and vice versa. Hence, if a horse is, for instance, unable from peculiarity of conformation to straighten his hocks (a condition called “sickle-hocks,” p. 210), he will not be so fast as he would have been, had he greater freedom in these joints. We may test the truth of this principle in our own selves; for if, when swimming in a bath (p. 47), we wanted to touch and turn, but were unable to straighten our knee on account of an injury or from some other cause, we would be capable of giving only a comparatively poor kick-off. The great beauty of a “straight-dropped hind leg” in the horse, as a conformation favourable to speed, will again be alluded to on p. 210.

The action of the fore limb in raising the fore hand, which is essential for the regulation of the position of the centre of gravity in locomotion, is also dependent on its difference of length when bent and when straightened out. It is manifest that this difference is mainly due to the action of the shoulder joint and of the fetlock. Hence, oblique shoulders and sloping pasterns are “points” of speed and of leaping power. If the shoulder-blade and pastern be upright, the limb will be capable of but slight extension.

In heavy draught, full straightening out of the limbs is not desirable; for the last part of this action is accomplished at a great mechanical disadvantage, to which I have alluded on page 45. At present it is sufficient to compare the action of the limbs to that of the oars of a boat, in which the
practically useful work is finished after the oats have passed the line at right angles to the length of the boat; the remainder of the propulsive effect being obtained by a wasteful expenditure of force. Consequently, an increase of speed is procured by an amount of work that is greatly out of proportion to the result. Thus, to double the speed during a certain period of time, it may be necessary for the horse to do five or six times the amount of muscular exertion. For instance, it may be more fatiguing for a horse to go twenty miles in one hour, than fifty miles in five hours. The cart-horse, when in heavy draught, moves his load with his hind limbs in a more or less bent condition (Fig. 91), which will give his hind-quarters the crouching appearance which must be familiar to us all. Sloping pasterns from a load-pulling point of view are objectionable in the cart-horse; for the more oblique they are, the greater is the mechanical disadvantage at which they work (p. 57). Sloping shoulders, also, from the same point of view, are undesirable.

**Action of the Muscles which extend the Vertebrae.**—When a horse prepares to kick, he, as a general rule, lowers his head and arches his loins ("puts his back up"), by doing which he relieves his hind-quarters of weight and puts it on his fore hand. When, on the contrary, he prepares to rear, he raises his head and neck and more or less hollows his loins, so as to lighten his fore hand and put more weight on his hind-quarters. If we examine Figs. 123 and 124 of the canter, Figs. 133 to 137 of the gallop, and Figs. 195 to 199 of the leap, we shall see that the muscles which enable a horse to rear, greatly aid the forward reach of the fore legs in the canter and gallop. Also, the heavier the fore hand, the greater difficulty will they have to raise it. In the leap, they assist the leading fore leg in raising the fore hand. If the horse carries a rider, these muscles will have an increased amount of work to do on account of extra weight being put in front, and will tire in a proportionately rapid rate. On examining the drawings of horses in Chapter XII. at the various paces, we shall see that the faster the movement, the more will these muscles be taxed, on account of the greater distance of the centre of gravity from the hind feet, during the period one or both of the hind limbs support and propel forward the weight of the body. Hence we find that to gallop fast or to jump "big," a horse must have good "rearing muscles" which consist principally of those that straighten the hock, draw back the thigh, and extend the vertebrae of the loins. These muscles also help to "lighten" the fore hand in the flying trot and fast "pacing," in both of which there is a period of suspension, which will vary in length according to the weight that is on the fore hand. From these considerations I may lay down the law that the faster the speed required, the stronger should the "rearing muscles" be. The pair of them (one on each side) that is most readily noticed, is the loin muscles, which in the ox constitute the upper cut of a sirloin, and which, in the horse, we may see just behind the cantle of the saddle. I need hardly say that the heavier the shoulder, the sooner will these muscles become tired; the shorter will be the stride; and the slower will be the pace. Consequently, horses for fast work ought to have light shoulders.
Carrying out the same train of reasoning, we may see that the longer a horse’s body, the greater will be the mechanical disadvantage at which these muscles will work; hence, a short body is a desirable point in the race-horse and jumper.

The combined working of oblique shoulder, well-sloped pasterns and strong rearing muscles, by preventing the fore hand going down at each stride, aids in obtaining the much admired “level” action in the race-horse. An animal which has a long body, heavy shoulders, upright pasterns, and weak loins (showing deficiency in the points just advocated), will, if he be put to a gallop, go in an up-and-down style; because his rearing muscles will be over-taxed by the weight of the fore hand at the end of the long lever made by his body, and because his fetlock joints will have deficient “play.”

I may remark that, although the loin muscles appear to be almost quiescent during easy walking and gentle trotting, they may be observed to act energetically in flexing and extending the loins when the animal is leaping and galloping, and when his powers are taxed in drawing a heavy load. Any one who has ridden races or gallops on speedy thoroughbreds, will know from experience the immense power behind the saddle possessed by animals of this class; for the rider cannot fail to feel the vigorous “lift” given by the loins at each stride.

It is a popular fallacy to imagine that the muscles over the loins are propellers. They have no propelling power at all; for they are not connected either with the thigh bone, or with any of the bones of the limb below it; their office in locomotion being merely to regulate the weight on the fore hand. I may mention that the muscles (those which constitute the under-cut in a saddle of mutton, or in sirloin of beef) under the loins, draw the thigh forward.

**Width between each respective Pair of Legs as affecting Speed.**—Let us suppose that the rectangle $a b c d$ (Fig. 37) diagrammatically represents the body of the horse; that the fore limbs are placed at the angles $a$ and $b$; that the hind limbs are at $d$ and $e$; and that the centre of gravity is at $c$. Were both fore legs and both hind legs to act respectively at the same moment, we would have the centre of gravity moved in a straight line, and in the direction in which the animal’s body was placed. In the amble (p. 85), the propulsion is given through $a$ and $d$, and through $b$ and $e$ alternately, with the result, in the former case, that the centre of gravity is displaced to the right, and in the latter to the left. In the trot (p. 82), the alternate strokes are through $a$ and $e$, and $b$ and $d$. If these respective propulsions, in the trot, were equal to each other, and if the centre of gravity were midway between the fore and hind legs, there would be no displacement of it from side to side. As however the impetus derived from the hind limb is greater than that from the fore leg, and as the centre of gravity is nearer the latter than the former, there is a certain tendency to lateral displacement, which has to be corrected by muscular effort. This tendency to a rocking movement from side to side is naturally greater in the
amble than it is in the trot. In the gallop there is a strong tendency to lateral displacement; for at this pace each leg gives its own separate stroke (pp. 95 and 96). When either of the near ones act, the centre of gravity is cantled to the right; when the off ones make their respective effort, it is thrown to the left. The retention of the centre of gravity in a more or less straight line, entails a certain expenditure of muscular work, and consequent fatigue.

It is evident that the nearer (Fig. 37) \( a \) is to \( b \), and \( d \) to \( e \), the less will be the lateral displacement of the centre of gravity, and the smaller the loss of speed from this cause. Hence we find that in animals of great speed, like the cheetah, antelope, greyhound, and race-horse, both the fore and hind legs are respectively placed much closer together than in animals of comparatively greater strength, but of slower movement. The faster the

pace (p. 103), the more do the footprints of the horse tend to come into the line of the direction in which movement is taking place. This principle is well exemplified in man; for all fast walkers, runners and skaters try to place the feet, at each step, as nearly as possible, in one straight line.

As I have already said, the tendency to lateral displacement of weight is corrected to a certain extent, in his various paces, by the horse, who has, however, to do it by a muscular effort, which is a lost force as regards propulsion.

**Effect of Instability of Equilibrium on Speed.**—The more unstable the equilibrium is, during each step of the horse at any particular pace, the greater will be the speed which can be developed at that pace, whatever it may be. This follows from the fact that the more insecure is the equilibrium, the quicker, when it is disturbed, will the new base of support have to be formed. Thus, in the walk of the horse (p. 87) there are never less than two feet on the ground; three as often as two; and sometimes even four. In the canter (p. 90), we have respectively in three steps, a support of one foot, of two (or of three) feet, and of one foot. In the trot
and amble, two feet touch the ground during each step. From this we may conclude that the canter is a faster pace, naturally, than the trot or amble. I am aware that this is not the case with many horses which have been specially trained for match-trotting and match-pacing; but that fact does not bear on the subject in question. Of all paces, the gallop is the one in which the equilibrium is most unstable; for during each stride of it, the centre of gravity is carried farther beyond the base of support (Fig. 144) than at any other pace. Besides, at each step in it, there are fewer feet together on the ground than at any other pace.

As it is imperative that the body of an animal intended for speed should be as light as possible, provided he has sufficient bone and muscle to meet his requirements; the preponderance of weight on the fore hand should be obtained by conformation, and not by any approach to "heaviness" in that part.

Fatigue from the various Paces.—In comparing the fatigue undergone during certain paces, we must be guided by the consideration of the respective distances through which the centre of gravity of the body has to be moved. Let us first of all consider its vertical, and afterwards its horizontal, displacement out of the straight line of the direction in which it has to travel. In the walk and at all other paces in which there is no period of suspension (p. 80), it is carried nearly parallel to the ground, with only a slight fall when each fore leg is taken up. At paces in which there is a period of suspension, the centre of gravity will have to be raised just as much as it will fall during that time. This fact is best marked in jumping; for in making even a long leap, the centre of gravity will have to be raised a considerable height. Thus, when Howard of Bradford, the famous jumper and sprinter, leaped over a full-sized billiard-table lengthwise, he was computed to have cleared a height of five feet four inches. Hence, animals like the antelope and cheetah, which adopt, when going at full speed, a leaping style of gallop (p. 106), can keep it up only for a short time. This fact is particularly well marked in the case of the kangaroo. For the same reason, a horse can go a distance with more ease to himself at a slow trot (which has no period of suspension), than at the flying trot (p. 83) or gallop (p. 94), in both of which there is a period of suspension. Not alone does the consideration of the comparative rise and fall of the centre of gravity give us an idea of the relative fatigue undergone during the various paces; but it also furnishes us with a guide to judge of the comparative ease with which different horses move at the same pace. Consequently, we may conclude that the more "level" a horse goes, whether at the fast trot, gallop, or other pace, the less will he fatigue himself: a fact which proves how thoroughly reasonable is the admiration every good judge has for a "level" style of movement—that is, one in which there is the least possible rise and fall of the fore hand at each stride. I have purposely used the word "fore hand" here. When noting whether the action of a horse is level or not, we are usually guided by the presence or absence of up-and-down
motion in the fore hand; for the special prominence of the head and neck will more or less rivet the attention of the eyes. Besides this, the centre of gravity of the horse's body is nearer his fore legs than his hind ones.

I may mention that as soon as fast antelopes, like the Indian Black Buck and South African Sprinbok, get tired in their bounding kind of gallop, they "settle down" to one resembling that of the horse (Figs. 133 to 148). When the cheetah—who, as far as I can make out, gallops like the cat (Figs. 166 to 171), in a succession of leaps—becomes tired of that pace, he drops into a walk or trot.

On pages 53 and 54 I have alluded to the effects of the lateral displacement of the centre of gravity in causing fatigue.

The pace which is the speediest, is also the most fatiguing; for, as in fast paces the centre of gravity will be carried further beyond its base of support than at slow ones, a greater muscular effort will be required in them to form a new base of support. We may see this if we compare, one with another, Figs. 58, 61, 77, 112, and 144.

**Action of the Head and Neck in Locomotion.**—During movement, the head and neck act as a balancing pole in changing the position of the centre of gravity from one side to the other, and in raising or depressing it. Certain muscles of the neck draw the fore limb forward and upward; other muscles of the neck straighten out the head and neck, and a third group bend them.

**Mechanism of the Fetlock Joint.**—As Lecoq explains, "the weight of the body, transmitted by the cannon-bone upon the upper articulating surface of the long pastern bone, is the resistance to be overcome. The fulcrum is the ground at the toe of the foot, and the power acts upon the sesamoid bones, which are at the back of the pastern; the shortening of the flexor muscles being the cause of the straightening of the angle formed by their tendons." The diagram given in Fig. 38 will show how this lever (one of the second order) acts. In it we see that the distance between the power and weight remains constant; but their respective distances from the fulcrum
MECHANISM OF THE FETLOCK JOINT.

Vary according to the slope of the pastern and hoof, and according to the length from the fetlock to the toe. Hence (pp. 42 to 44), the shorter is the distance of the toe from the direction of the cannon-bone, or from that of the back tendons, the greater will be the mechanical advantage at which the back tendons will act; and vice versa. On the other hand, we may see that the more is the mechanical gain, the worse will the fetlock act as a spring, which function is all-important in saving the limb (especially the fore one) from the injurious effects of concussion. It is evident that the distance of the weight (or power) from the fulcrum (F) is influenced by the length and slope of the pastern; it being greatest when the pastern is long and oblique, and least when that part is short and upright. I may point out that increased growth of hoof, either at the toe or heel, will affect the slope in question, and that the thickness of horn at the toe will, of course, influence the length from the fetlock to the toe. As a practical point I may remark that the toe (except in the treatment of some forms of disease) should always be kept low, and that shoes should be no thicker at the toes than what would be sufficient to enable them to stand "wear." I have alluded to this subject further in my Veterinary Notes for Horse Owners.

Fig. 39.—1st Order. Fig. 40.—2nd Order. Fig. 41.—3rd Order.

Levers of the Hock.
Mechanism of the Hock Joint. Figs. 39, 40, and 41 show the three actions of this joint as a lever.

Besides flexion and extension, this joint has an outward motion, due to the outward and forward direction of the pulley formed by the astragalus.

We find, contrary to what we might have expected from an inspection of this bone, that this oblique play of the hock joint does not affect the direction in which the hind foot is carried; its object being, as explained by H. Bouley, to allow the *stifle to clear the belly, when the hind foot is brought forward.
CHAPTER IX.

MECHANISM OF DRAUGHT.

Draught in the collar or breast-harness is, as explained by Colin, an act of pushing, and not one of pulling. The only kind of draught I have ever heard of, which could be put under the latter heading, is that of making a horse draw by attaching the weight to his tail, like what farmers in some countries used to do long ago, when they wanted to plough!

Propulsion in draught, like in other forms of locomotion, is effected by placing a series of levers, bent on one another, between a fixed point and a movable one. In locomotion of the body itself, the series of levers are those only of the limbs. The movable point, in the hind limb, is the portion of the pelvis against which the head of the thigh bone rests; and in the fore extremity, the lower end of the humerus. In harness, on the contrary, the series of levers is that between the spot against which the foot rests and the centre of pressure on the inner surface of the collar, which, in this case, is the movable point.

In Fig. 42, the line A B represents the direction of the propelling force given by the hind leg which is on the ground; and E B, that by the fore limb; B being the assumed centre of pressure. The resultant of these two forces must pass somewhere between the points A and E, and through the point B. It is, however, impossible to fix its exact direction; as we cannot determine the respective amounts of these two forces, and as the proportion they bear to each other continually varies. If two hind feet, as in Fig. 92, were engaged in pushing against the collar at the same time, the direction of their resultant would naturally pass between them and between the two points occupied by the respective centres of pressure on each side of the collar. From a practical point of view, we may assume that this centre of pressure, on each side, is on a level with that portion of the harness to which each respective trace is attached. This would place it somewhere between the middle and lower third of the bearing surface of the collar.

The force applied to the collar by the animal is obtained in two different ways: first, by the weight of the animal, and second, by the force of propulsion to which I have just alluded.

The weight of the animal acts on the collar by reason of the centre of gravity being placed in front of the base of support (p. 46), the anterior limit of which is marked by the position of the toe of the fore foot which is on the ground. It is evident that the further a perpendicular dropped from the centre of gravity falls in front of the base of support, the more effectively will the weight of the body act in propulsion. This forward translation of
the centre of gravity with reference to the position of the base of support, is
influenced, first, by the degree of slope which the fore leg makes with the
ground immediately before it quits it, and before the other fore leg is brought
down; and, second, by the lowering of the head and neck. I need hardly
say that horses with toe-pieces to their fore shoes can, while retaining their
foothold, bring the centre of gravity farther beyond the base of support, by
the slope of the fore leg which rests on the ground, than they could do with
flat shoes; supposing, of course, that the surface of the ground was not
abnormally smooth and hard, like wood or asphalt. From the foregoing
considerations we may draw, with respect to cart-horses that are required to
exert their strength to the utmost, the following deductions, which are fairly
self-evident to practical men.

1. Bodily weight, especially in the fore hand, is an advantage in draught;

---

**Fig. 42.—Mechanism of Draught.** (From Colin’s *Physiologie Compard.*

for the greater it is, the more effective will be the push against the collar
caused by the centre of gravity falling beyond the base of support. Agreeably
to this fact, the experienced driver of a heavily-laden two-wheeled cart will
endeavour to place a fair share of the burden on the animal’s back, so that
the horse may pull to the best advantage. The experiment of a man
succeeding in pulling along a stronger man than himself, by trying to do so,
while carrying a heavy weight on his back, is another familiar instance of
this principle. The gain in power from increased weight on the fore hand is,
also, well illustrated by the practice, which is not very uncommon among
drivers of one-horse carts, of the driver mounting his animal and getting well
forward on its back, when he finds that it is unable to pull its load up a hill.
2. The cart-horse ought to have a heavy neck as well as massive shoulders. As a natural corollary to this proposition, which infers the lowering of the head and neck, we must condemn the use of bearing reins with the class of horse which we are now considering.

3. The shoes of the horse should have toe-pieces when the ground is favourable to their employment.

On the other hand, when the horse, on account of the slippery nature of the ground, is unable to use his fore legs, except to a very slight degree, as propellers, the fore hand should be light and the head carried high. Thus, the weight has to be kept almost entirely off the shafts of London hansom cab-horses, which would be rendered very liable to fall down on the greasy wood pavement and glass-like asphalt, if a fair proportion of the load were to be put on their backs. Not alone is weight kept off their backs, but as a rule it is so distributed as to cause the back-band to exert on the "girth-place" an upward pressure, which, naturally, will more or less aid in "lightening" the fore hand.

The force of propulsion given by the hind limb is dependent on a series of levers which extends from the toe of the hind foot, along the bones of the hind leg, pelvis, spinal column, up to the centre of pressure on the inner side of the collar. It is manifest that the flatter this irregular line of levers is with reference to the line of propulsion from the toe of the hind foot to the collar, the greater will be the mechanical advantage at which the hind limb will act. Consequently, we may infer that the cart-horse should be long in the body, as compared to his height; that he should be lower over the croup than he is at the withers; and that he should not have a horizontal croup. We should not, however, desire his hind-quarters to be so drooping as to cause him to be actually "goose-rumped" (p. 208).

The amount of forward propulsion given by the fore limb varies according to the position of the humerus; for the more horizontal is this bone, the more effective will be the push. As its degree of slope with the ground is directly affected by that of the shoulder-blade, it follows that the shoulders of the cart-horse which has to fully exert the powers of his fore legs in propulsion, should be more upright than sloping.

It is a well-known mathematical fact that the most advantageous direction for the pull in draught to be, is one which makes an angle with the ground equal to the angle of friction. I may explain that if, for instance, $10^\circ$ was the greatest slope of ground upon which a body could rest without sliding down, its angle of friction would be equal to $10^\circ$. The best direction then of the traces would be at an angle to the ground equal to the angle of friction. In many cases the pull of the traces is not at a sufficient angle to the ground, and the work is consequently performed at a mechanical disadvantage, which might be remedied by the employment of a taller horse than the one used, by having smaller wheels, or by a change in the harnessing arrangement. For instance, in such a case, instead of attaching the traces to the hooks on the shafts of a dog-cart, they might be connected, as is sometimes done, to the axletree.
CHAPTER X.

ATTITUDES OF THE HORSE.

Standing at Attention—Standing Collectedly—Standing at Ease—Carriage of the Head and Neck.

Standing at Attention.—When a well-shaped and sound horse stands at attention, if I may use the term, he has his head and neck raised, ears pricked forward, the profile of the face at an angle of about $45^\circ$ to the ground, and at about a right angle to the upper line of the neck (the crest); the weight distributed in due proportion on all four limbs; and, as a rule, the fore foot of one side not so far advanced as its fellow, and its hind foot more to the front than the other hind foot (Fig. 229). If the hind feet be equally advanced, a perpendicular line dropped from the point of the buttock will, on the respective sides, about touch the point of the hock. If one hind foot be placed in front of the other hind foot, the vertical line will, more or less, divide the interval between the points of the two hocks. As the weight of the horse's head and neck is beyond the base of support formed on the ground by his feet; he would "stand over" on his fore legs—that is, their direction would be downward and backward—if they were equally advanced (Fig. 321), and if each of the limbs was bearing its share of weight. I need hardly say that when one fore leg is advanced more than its fellow, and when it is vertical, the animal will be somewhat over on the other fore leg.

French writers consider that when a horse stands with the weight properly distributed on all his limbs, a line dropped from each point of his buttock will coincide with the
posterior edge of his hind leg, from the point of the hock to the fetlock; and that the direction of the front legs will be vertical, as in Fig. 43, which I have taken from Goubaux and Barrier's *L'Extérieur du Cheval*. It may be possible to make a horse assume this attitude (Fr. *le placer*); but I must say I have never seen a horse adopt it. Fig. 44 is the nearest approach in a well-bred horse to this position that I have been able to get in a photograph, of which this illustration is an exact copy.
In the front view of the horse—when he is standing in an unconstrained position, with his feet equally advanced and a little distance apart—the fore arms will slightly converge, and the cannon-bones will be about parallel to each other (Fig. 46). A vertical and longitudinal plane passing through the centre of the knee and fetlock of each leg will cut the centre of the toe. In Fig. 47 the toes are turned in, and in Fig. 48 they are turned out.

The rear view of the horse in Fig. 50 illustrates the condition known as “cow-hocks,” in which the points of the hocks are more or less turned in. Figs. 49 and 289 show symmetrically shaped hind legs, viewed from behind. Although I have devoted much careful study to this subject, I can apply no geometrical rules to determine, as some writers have tried to do, the correct shape of the legs from this aspect. It can, in my opinion, be judged only by the trained eye of the observer—I mean in deciding whether the hocks are correctly placed, turned in, or turned out.

Standing “Collectedly.”—This is the position (Fig. 45) a horse assumes when he makes ready to move quickly away from the place in which he is standing. His hind feet will be well in front of a perpendicular line dropped from the
points of the buttocks, his fore feet will be brought back more than usual, and he will stand more or less over on them. His head and neck will be raised, and he will be looking to his front, with his ears pricked forward, if he be one of the quick, observant class.

Many persons who hold decided views on horse conformation, maintain that a true shaped horse will, when he stands, have his hind legs "well under him," as in Fig. 45, such a position being regarded by them as a point of conformation, and not as an attitude. To prove the fallacy of this idea, I may mention that the same mare, photographed on the same day, is shown in Figs. 45 and 333. In the former, her hind legs are well under her, in the latter they are a little behind her; the difference being merely one of position or attitude. With reference to this subject, I need hardly say that a horse may assume many attitudes, but he has only one kind of conformation. On the other hand, however, we must not ignore the fact that if a horse is unable to bend the joints (the hocks, fetlocks and pastern joints are the ones which are usually affected) of his hind limbs properly, he will naturally refrain from bringing his hind feet forward, when standing or moving to the front, as freely as he would do were his hind limbs in good working order. In judging of this, we should form our opinion more from the action of the animal during movement, than from the position he takes up when standing; although both should of course be considered.

Standing at Ease.—The sound horse will, almost always, when standing at ease, have both fore feet equally advanced, and with his weight chiefly on them; for he can obtain this support in front, without muscular effort on his part (to which fact I shall presently again refer), and consequently without fatigue. His head will be lowered, and will be supported by the suspensory ligament of the neck, the action of which is also accomplished without fatigue (p. 28). As the hind limbs are unprovided with an
apparatus by which they can bear weight without fatigue; their muscles have to obey the law which requires, for the health of muscular tissue, alternate periods of rest and work. Hence, one hind limb is rested by its joints being bent and its heel raised, while its fellow supports the weight of the hind-quarters. When the working hind limb becomes tired, the other one takes its turn of work; and so on.

When a couple of long-tailed horses are in the open at liberty, they will sometimes elect to stand head and tail together, so that each one by the action of its tail can keep flies off its own hind-quarters, and off the chest and shoulders of its fellow.

If, while standing still, horses are exposed to inclement weather, they will generally try to turn their hind-quarters towards the direction from which the rain or wind proceeds.

The fore limbs of the horse are furnished with special fibrous bands (ligaments), which, during rest, take the weight off the muscles that straighten the various joints. I may here remind my readers that these ligaments are composed of hard, inelastic, fibrous tissue, and act simply as strong cords in connecting the parts together. The work they do being entirely of a passive nature, they do not get tired, like muscles, the work of which is of an active form, and cannot be continued without suitable intervals of rest. As an instance of this "bracing" function of ligaments, I may mention that the fetlock is passively supported during rest (taken in a standing position) by an inelastic fibrous cord, which goes behind the fetlock point, and is attached by one end to the head of the cannon-bone, and by the other to the base of the pedal bone. Not alone are the fore legs provided with these special ligaments, to prevent the limbs from "doubling up;" but most of the muscles which straighten these limbs during work are composed of a large amount of ligamentous fibres. Such muscles, therefore, during their periods of rest, can assume to some extent the functions of ligaments. In fact, one powerful muscle in the fore leg of the dog is represented
Fig. 46.—Well-shaped Fore Legs.

Fig. 47.—Turned-in Toes.

Fig. 48.—Turned-out Toes.

Fig. 49.—Well-shaped Hind Legs.

Fig. 50.—Turned-in Hocks.
in the horse by a ligament. Besides this, the muscles which
straighten the fore limb are not single, but multiple muscles,
one of which can take its turn at work, while its fellows rest.

This mechanism enables the horse to sleep standing
without extraneous support. It is clearly and exhaustively
described in Colin's *Physiologie Comparée*.

Carriage of the Head and Neck.—The attitude
which the head and neck assume is determined by the
following considerations: (1) *For the horse to be able to see
in the required direction.* If we regard a horse that is
standing at attention (p. 62), and is looking straight in front
of him, we shall, as a rule, note that his neck is held in an
easy position, being neither stretched out nor drawn back,
and his head is placed so that the line of his face will make
an angle of about 45° to the ground. We may, therefore,
consider that the axis of each eye is at about that angle
to the line of the face. In man, the angle is about 90°,
the difference between the two being chiefly one of brain
capacity. In the horse, the occipital crest, which is the
highest point of the horse's head, may be regarded as a
continuation of his forehead. In man, owing to the bulging-
out condition of the brain, it is placed at the back of the
head. When a horse wishes to take a good view of the
ground in front of him, he will, by the adjustment of his
neck, adopt a lofty carriage of the head, while keeping the line
of the face at an angle of about 45° to the ground. If he
requires his line of vision to be at about that angle to the
ground in order to see, for instance, an object six or seven
feet in front of his feet, he will bring the line of his face
perpendicular, or nearly so, to the ground. Of course, the
axes of the eyes can be altered, more or less, without the
head being moved; but the horse possesses such mobility
of head and neck that, when he is free, he will adjust his
line of vision principally by the movement of these parts.

It is therefore evident that if we want a horse, when
riding or driving him, to have a good look at the ground
over which he is about to go, we should allow him, or
endeavour to induce him, to carry his head at an angle of
about 45° to it. A more perpendicular carriage of the head
would be permissible only for school work, or for evolutions
in which freedom of movement has, to some extent, to
be sacrificed for obtaining thorough power of control. If
the angle which the face makes with the ground be much
less than 45°, the animal will not be able to see where he
is going.

(2) To permit of free movement of the fore limbs.—My
readers will remember that the shoulder-blade of the horse,
on each side, is connected to the body by muscles which
allow it to work backward and forward on the chest. The
shoulder-blade and humerus (Fig. 12) being drawn forward and
upward by muscles of the neck; it follows that the direction of
this pull will be regulated, to a great extent, by the direction
in which the horse carries his head. Hence, if we require
"lofty" shoulder action, we must get him to carry his head
comparatively high. If he carries it low, only a slight
upward lift can be given to the shoulders. In such a
case, to make up for want of shoulder action, the horse
will probably increase his knee action, which is obtained
by muscles that have no power to move the shoulders.
Thus, we may see a horse who has free shoulder action and
gallops with a straight knee when he carries his head fairly
high, go in a "round" and cramped style, if he be permitted
or induced to carry his head low down. I may here explain
(as we may see by reference to the figures in Chapter XII.)
that in all paces, and especially in fast ones, in order to obtain
good forward reach, it is requisite that the fore limb should be
drawn upwards as well as forwards. The defect, as regards
want of safety, in the fore feet not being lifted sufficiently
off the ground by the play of the shoulder, may be compen-
sated for by increased knee action, which, however,
will have no effect in lengthening the stride; but will, in
causing loss of time in putting down the fore feet, tend to
diminish the speed. As practical points directly connected
with this subject, I may mention that the use of the curb bit has been found to injuriously affect the action of race-horses by, as a rule, making them carry their heads low down, and consequently to gallop "round." Trainers of match-trotters employ an "over-draw check-rein" (bearing rein) to improve the action of horses which do not carry their heads high enough, and which, on that account, have too low action. The bearing rein is, in many cases, necessary for the attainment of that "extravagant" action which is greatly sought for among fashionable carriage horses: a fact which accounts for its retention in the stables of the rich, despite the adverse criticism that is being constantly directed against its use. As a rough guide to the direction of the neck (supposing it to be straight or only slightly bent) when the line of the face is at an angle of about 45° to the ground, I may say that, at ordinary paces, the upper part of the nostril should not be lower, or only slightly so, than the top of the withers. In the fast gallop, the horse will carry his head lower down than this, so as to bring his weight forward, and thus to increase his speed (p. 54). This difference in the carriage of the head will be evident, if we compare Figs. 114 to 122 with Figs. 133 to 148. A fairly high carriage of the head, with the face at the angle, just mentioned, is a most desirable point in the cross-country horse, who requires to obtain a good view of the ground or obstacles in front of him, and to have free shoulder action; in other words, to be "light in front," which implies that his hind legs are well "under him." If, on the contrary, we want a horse to rein back (p. 99), we should make him lower his head and bring it perpendicular, or nearly so, to the ground, in order to put weight on his fore legs and lighten his hind ones. Those of my readers who have studied high school riding, will remember that, according to the teaching of Baucher, who introduced many valuable improvements in military equitation, the normal position of the head of the school horse was perpendicular to the ground; and that the head was carried comparatively low.
That admirable exponent of the *haute école*, James Fillis (see his *Principes de Dressage*), having wisely rejected, even in the most elaborate *airs de manège*, this artificial style, teaches that the school horse should carry his head high and the muzzle well advanced out of the perpendicular. If the head be carried too high; forward reach will be proportionately sacrificed to upward shoulder action, with consequent loss of speed. Hence hunters, animals that require to be clever over bad ground, such as pig-stickers and Colonial stock horses, and those in which showy action is sought, such as chargers, school horses, and park hacks, should carry their heads higher than animals in which speed is the chief consideration. The more the lift to the fore legs is obtained by the play of the shoulders, and not by the mere raising of the knees; the safer, more brilliant, less fatiguing, and faster will the action be in every class of horse.

The chief muscle which draws the fore limb (of each side) forward and upward, is attached by one end to the humerus and by the other to the top of the head. Other muscles that draw the shoulder-blade forward and upward, are attached to it and to the ligament of the neck, which stretches from the withers to the top of the head (p. 28). As muscles act best when their points of attachment are wide apart; the horse, during rapid movement, regulates, under normal conditions, the amount of the extension of his neck, according to the speed at which he is going. In this case, the head and neck are the fixed point; the fore limb, the movable one. As long, therefore, as the speed of any particular pace remains uniform, the length of the neck (measured roughly from withers to top of head) should continue unchanged. Consequently, when riding or driving, if we desire the horse to maintain a uniform rate of speed, we should keep a uniform tension on the reins (note, for instance, the fixed position of the hands of a capable lad from a racing stable when he is riding a steady training gallop), and should not “give and take” with them. If the speed be increased, the hands, supposing their hold on
the reins remains unaltered, should be advanced, as may be required; if it be decreased, they should be drawn back. Thus, any alteration by the rider, of tension on the reins which might impede the legitimate movements of the neck, is avoided. As the joint which the head makes with the atlas (first vertebra of the neck) is situated some distance below the top of the head, it follows that if the muzzle be unduly stretched out, the occipital crest (top of the head) will be brought back, and the tension of the ligament of the neck lessened, with consequent decrease of power to the muscles which are attached to this ligament. The muscle which is attached to the humerus and top of the head, also would work to disadvantage if the muzzle were stretched out to a greater extent than would bring the line of the face to a right angle with the direction of this muscle, which forms the upper border of the jugular groove. Even in the fast gallop (vide Figs. 133 to 148), the horse rarely carries his head at a less angle than $45^\circ$ to the ground.

(3) To regulate the position of the Centre of Gravity.—
The more the head is advanced to the front, the more unstable will be the equilibrium, and the greater will be the speed during progression (p. 54). Hence, the race-horse, when galloping at full speed, will bring his head forward as much as the other conditions which affect its carriage will allow him to do. As I have before remarked, the angle which his face makes with the ground will seldom be less, even at the highest speed, than $45^\circ$. The cart-horse, if he has good foot-hold, will also, when pulling a heavy load, lower his head and stretch it out, so as to bring the centre of gravity forward as much as possible. Here I assume that the ground is soft enough to allow him to "dig his toes" into it, or, if it be rough, that he is provided with toe-pieces on his front shoes. If, on the contrary, the roadway is slippery, like the London streets which are covered with asphalte or wood, the cart-horse in heavy draught, being afraid of falling down if he throws
his weight into the collar, will try to keep the centre of gravity back by holding his head high, while trusting almost entirely to his hind legs to push the body forward. When a horse rears, halts suddenly, or reins back in heavy draught (p. 99), he will raise his head and neck so as to bring the centre of gravity back. Any one who has ridden much "over a country," will know the great use a horse makes of his head and neck for regulating the position of his centre of gravity when jumping, and especially when he makes a "mistake." When a horse turns or "circles," he ought to have his head and neck bent in the direction he is going, in order to see where he is proceeding, and to increase his stability by shifting the centre of gravity towards the side to which the turn is being made.

(4) To enable the Mouth-piece of the Snaffle to act efficiently on the "bars" of the Mouth.—I may explain that the "bars" of the mouth are those parts of the gums of the lower jaw which are bare of teeth, and which are situated between the back teeth and the tushes of the horse or gelding, or the spots which they would occupy, were these canine teeth developed in the mare. As the "bars" are much more sensitive to pressure than the corners of the mouth; we should, when using the snaffle, endeavour to make the horse carry his head so that he will not shift the mouth-piece off the former and on to the latter. The mouth-piece will, naturally, act best when the head is carried perpendicularly to the ground; but it can also act efficiently if the line of the face is not at a less angle to the ground than about 40°. The apparent anomaly of the mouth-piece of the snaffle not slipping off the "bars" and on to the corners of the mouth in this case, may be explained by the fact that the well-broken horse, when being ridden or driven, keeps the joints of his lower jaw in a more or less relaxed condition, so that the "bars," as a rule, will make a greater angle with the ground than the line of the face will do. When a horse which is ridden in a snaffle, is made to carry his head in a
more or less perpendicular manner, he may, as a "defence,"
relax his jaw, with the object of letting the mouth-piece slip
down in his mouth as much as possible, in order that a
certain amount of the pull of the reins may be transferred
from it to his poll, over which the crown-piece of the bridle
passes. Any "defence" which a horse makes by opening
his mouth, may be counteracted by the use of a properly
applied nose-band.
CHAPTER XI.

STATIONARY MOVEMENTS OF THE HORSE.

Lying Down and Getting Up—Rearing—Kicking—The Piaffe.

Lying Down and Getting Up.—When a horse prepares to lie down, he will bring all his feet well under his body, while resting his weight chiefly on his hind feet. After making a few tentative movements with his fore limbs, he will gently lower his fore hand until his knees lightly touch the ground. He will then give his body a twist, and will roll over, and rest, partly on his side and partly on his breast bone. Colin describes as follows the position of the horse when lying down. As a rule, if he is on his right side, for instance, the right fore leg will be under the chest, with its foot facing the inside of the left elbow. The other fore, equally bent, but clear of the body, will have its foot close to its own elbow, and there will be a space of about twelve inches between the two knees. The hind limbs will be bent up under the body, with the feet carried to the front. The near hind will be far removed from the side; its hock will be on a line with the hip joint, and its hoof, with the point of the hock. The neck will be raised, and the head will be inclined to the left side. Sometimes the animal rests his lower jaw on the ground. He may even, at certain moments, support his head on the flank or hock, which is a favourite position with cattle, buffalo and deer, when they have stopped ruminating, and appear to want to go to sleep. They cannot, however, long maintain this position.

As the suspensory ligament of the neck can support the weight of the head and neck without giving rise to the sensation of fatigue; a horse can sleep comfortably on his side.
Fig. 51.—Foal getting up off ground.

Fig. 52.—Hollow Back from old age.
REARING.

and breast bone and with his head turned to the opposite side. When a horse is very tired, or even when he feels secure from disturbance, he may sleep entirely on his side, with his cheek resting on the ground. On rare occasions, a horse will repose lying down on his breast bone, with his knees advanced and his heels more or less close to the points of his elbows. This position is considered apt to give rise to "capped elbow," on account of the pressure of the heel of the doubled-up fore leg on the point of the elbow. It is not an easy position for the horse; for the sharp keel of his breast bone will be liable to be hurt by contact with the ground. It is, however, the natural sleeping position of horned cattle, which can rest at ease in this manner; as the keel of their breast bone is flat.

In getting up, the horse straightens his fore legs out to the front (Fig. 51), and with a strong effort places his fore feet on the ground and raises his fore hand, so as to sit up like a dog. With another effort he raises his hind-quarters and stands on all four feet.

Rearing.—When a horse prepares to rear, he will get his hind feet well under him and will raise his head, so as to "lighten" his fore hand, which he will lift off the ground by the straightening out of one or both fore legs, and by the action of his "rearing muscles" (p. 52). He will then keep his fore legs bent at the knees and his head high (Fig. 53). In guarding against the rear, the rider should, therefore, lean well forward. If he wishes, by inflicting punishment, to stop the horse from rearing, he may hit the animal on one of the hind legs, so as to prevent him from fixing them on the ground, in order to "get up"; but he should on no account strike him on the shoulders; for doing so would tend to make him raise his fore hand. We may break a horse of rearing by teaching him to rein back in a "collected" manner (p. 99, et seq.). By doing this, we "lighten" the hind-quarters and accustom him to lift them and move them freely. In the rear, the horse usually keeps one hind foot advanced
more than the other, and his hind feet more or less apart, so as to widen the base of support.

The rear is a particularly insecure and fatiguing attitude for the horse to maintain; as the column of bones formed by the body and the hind legs has to be kept in position, at its joints (or angles), by the exercise of muscular force. In a biped, like man, this column of bones can be brought into a nearly vertical position, so that its component parts

![Fig 53.—Rearing](image)

...can rest on each other, with but little muscular exertion to maintain them in that position. Owing to the large amount and continued nature of this muscular effort, there will be an appreciable backward and forward sway (caused by the alternate contraction and relaxation of the opposing muscles) at the various joints. This, added to the narrowness of the base of support (formed by the hind feet and the respective lines which join their toes and
Kicking

heels), will render the rearing position so insecure that, to support it, the horse will have to keep frequently changing it. The danger of falling backwards which the animal incurs, if he gets too erect, will naturally help to deter him from trying to assume a comparatively vertical position. Hence, he will have to keep the joints of his hind limbs more bent than if he was not exposed to this risk of falling backwards.

The hocks are particularly liable to injury from rearing, owing to the great strain thrown on them when the animal assumes an upright position. "Curbs" and other enlargements are of frequent occurrence among circus horses which are trained to walk on their hind legs.

Kicking.—The term "kick" is usually restricted to a blow given by one or both hind legs (Fig. 54). A horse is said to "strike out" with one or both fore legs. We may regard both these movements as kicks.

A horse can kick in three ways: (1) To the rear with one or both hind legs; (2) to the front with a hind leg; and (3) to the front with one or both fore legs. Unlike horned cattle, a horse is unable, without moving the body, to kick to one side, except to a slight extent, owing to the presence of a ligament which connects the thigh bone to the pelvis, and which greatly restricts the side action of the limb. If a horse, therefore, wants to kick a man who is standing a little away from its side, it will have to turn round to do so. For this reason, if a person wishes to stand in safety by the side of a horse's hind-quarters, as for instance when examining its hocks, he should get an assistant to stand on the same side, and to draw the head round to it a little, so that the animal will not be able to turn round to kick if so inclined. If the horse be a vicious kicker, the advisability of getting the fore leg of the side at which one is standing, held or tied up, will be self-suggestive to any one who has had experience with horses. The forward kick with a hind leg (called a cow kick) has a good deal of range; as a horse can, in this manner, hit a man who is standing at its shoulder.
When striking out in front, the horse will generally do so with one foot; for the blow can be delivered with greater speed when the other fore foot is on the ground, than if both were off it. If he strikes out with both fore feet, he will do so with a quick, short effort, with the object of giving a blow; or he will make a greater or less attempt at rearing, so as to bring his feet or legs on the top of the offending person or animal with the view of knocking it down. The governing idea, more or less developed, of thus overthrowing his enemy is, evidently, to kneel on him and to bite him. This mode of attack is seldom seen in its complete form, except in the case of entires, which are more prone to bite and strike out with both fore feet than are mares and geldings. Mules usually kick out behind with greater freedom than horses, but are not so much inclined to bite or to strike out in front. Mares, from sexual causes, are more inclined to kick with their hind legs than are the other two. Horses sometimes kick with a hind foot in a good-tempered way, not with the purpose of inflicting pain, but merely to push the object of the attention out of the way, as we may occasionally see a mare do to her foal. Horses often kick
in play without any vicious intention. I am convinced that many apparently vicious kicks which miss their marks, are delivered, not with the desire of sending the blow home, but to warn the intruder against nearer approach.

When a horse kicks out behind, he will put extra weight on his fore hand, and, as a rule, will lower his head. When he cow-kicks or strikes out in front, he will raise his head and bring his weight back.

In almost all cases, just before a horse kicks, he will draw back his ears, and more or less show "the white of his eye." If the suspicious object be behind him, he will bring his head slightly round so as to see it, and will prepare for his attack by bending the fetlock and raising off the ground the heel of the hind leg of that side. I may mention that a horse cannot kick with the hind leg upon which he is resting his weight; for he has to transfer the weight to its fellow before he brings it into play. My readers will observe that I have used the word "slightly" with reference to the extent the animal turns his head when he gets ready to "lash out"; for if he brought it round a good deal, he would be obliged to throw more weight on the hind leg of the side to which he is looking than on its fellow, and would consequently have a difficulty in using it.

**The Piaffer.**—This is an *air de manège*, which is simply a *passage* (p. 98) without gaining ground. The most brilliant kind of *piaffer* is when the movement is slow, lofty, in true cadence, and with a well-marked pause when each leg is raised to its highest point.
CHAPTER XII.

PACES OF THE HORSE

I may remark that there is no such thing as absolute uniformity in the paces of the horse.

Definitions. To simplify explanation, we may, when speaking of the limbs, call the near (left) fore and near hind, the left pair; the off (right) fore and off hind, the right pair; the off fore and near hind, the right diagonals; and the near fore and off hind, the left diagonals. The meaning of both fore and both hind is evident.

We may use the word support to signify the fact that the weight of the body is borne by one or more limbs, as, for instance, left support, when only the left pair are on the ground; and right diagonal support, when the right diagonals alone prevent the horse from falling.

A stride is the distance from the foot-print of any one leg to the foot-print of the same leg, when it next comes to the ground; or it is the action of the limbs while that distance is being covered.

A step is the forward or backward movement of one foot; or it is the distance one foot is removed from its fore or hind fellow.

The term, period of suspension, will serve to designate the time during which the animal is completely off the ground at any particular pace, or when jumping.
Natural paces are those which the horse adopts of his own accord, without any teaching of man; artificial paces, those which he performs only after special training.

Time (as applied to the rhythm of a pace) is the number of separate steps in each stride of that pace. Thus, the amble, in which the right pair and left pair move alternately, is a pace of two time; and the walk, in which each limb moves separately, is a pace of four time.

To prevent any chance of confusion, I shall limit, in this chapter, the meaning of the word pace to particular and distinct methods of progression, and shall not use it as a synonym for the word speed.

The Trot.—We may select the trot to begin with, as it is the simplest of all ordinary paces. Although it is essentially a natural pace, some horses which have been trained to amble, require a good deal of teaching to give up the amble, and to trot in true style. It consists of the alternate action, in progression, of the two diagonals, in each one of which the fore and hind leg move in the same manner. Thus, in Figs. 55 and 57, we have the left diagonal support and right diagonal support shown as the diagonal pairs of feet come alternately to the ground. Figs. 56 and 58 depict the position the limbs occupy, just before the feet quit the ground. I need hardly say that it is a pace of two time.

We may divide the trot into three kinds: (1) The short or slow trot, in which the prints of each respective hind foot do not reach as far forward as those of the fore foot of the same side; and there is no period of suspension. (2) The ordinary trot (Figs. 55, 56, 57, and 58), in which the hind feet more or less cover the fore feet, or even go slightly beyond them, in which case there will be a brief period of suspension. (3) The flying or fast trot, in which there is a well-marked period of suspension between each stroke of the diagonals (Figs. 59 to 63); the movements represented being those of alighting, support, quitting, suspension, and alighting on the opposite diagonals.
The trot is the least fatiguing pace to the horse, by which he can go a long distance continuously at a fair rate of speed; because both fore and hind limbs, respectively, have the same amount of work to do; the body can be more easily maintained in a state of equilibrium by a diagonal support than by a side support, as in the amble; there is but little loss of power in keeping the centre of gravity (p. 40) level; and because the pace is a tolerably fast one. It is more suitable for draught, than for saddle. First of all, it is very

fatiguing to the rider, especially if he bumps up and down à la militaire. Consequently, we find that men who are accustomed to go long distances on horseback, as in the Colonies, almost always combine the canter and walk instead of adopting the trot. Although rising in the stirrups will make this pace much more easy for the rider, it will not benefit the animal to the extent one might imagine; for, strange to say, almost every horseman, when rising at the trot, invariably comes down on one particular pair of
diagonals. Thus, some will put their weight only on the right diagonals; others, only on the left. I may mention that, when rising in the stirrups, the rider's weight is borne by only one pair of diagonals. As each pair has to do its

![Figure 59: Commencement of Right Diagonal](image1)

![Figure 60: Right Diagonal](image2)

![Figure 61: Right Diagonal](image3)

![Figure 62: Suspension](image4)

![Figure 63: Left Diagonal](image5)

own allotted work, it is nearly as well to have both tired, as one fresh and the other fatigued. The chief advantage which rising in the stirrups has to the horse, is that the man who adopts it, conforms better to the movements of the
animal than one who bumps up and down. Men who ride, might with advantage learn how to change their time of rising in the trot, so that, after having made one pair of diagonals bear their weight for a time, they might be able to change it on to the other pair. Ladies whose stirrup is on the near side, and who rise in the trot, almost always do so during the left diagonal support, and come down during the right diagonal support. As the weight at the trot is distributed between one hind and one fore leg, it (or, possibly, the amble) should be used, when practicable, for going over hard ground, in preference to the canter, and still more so to the gallop.

Figs. 64 to 69 show phases, from photographs, of the trot, from the left to the right diagonal support.

The Amble.—A few horses naturally adopt this pace in preference to the trot; but it is an artificial one with the majority of amblers. Goubaux and Barrier tell us that some foals begin at the amble, and that they do not learn to trot until later, when they have acquired age and strength. These eminent French authorities also point out that it sometimes happens that horses, which were formerly good trotters, take to ambling at the decline of their life, on account of their legs becoming worn out.

The amble is a pace of two time, and consists of the alternate movement, in progression, of the right and left (or left and right) pair of legs. In Figs. 70 to 74, which depict what we might call the flying amble, there is a period of suspension between each stroke. This fast amble is known in America as “pacing.” There is little or no period of suspension in the ordinary amble. The amble is a very easy pace for the rider, but is unpopular (why, I cannot tell) in England. The slow amble (the “tripple”) is the favourite pace among the Dutch farmers in South Africa. Baron de Curnieu (Leçons d’Hygiène Hippique Générale) tells us that Napoleon I. was accustomed to ride amblers during his campaigns, when he had to go long distances at a fast pace. If a horse
Phases of the Trot of a Hunter.
FLYING AMBLE.

takes readily to the amble, his rider will find it a comfortable method of travelling. The remarks I have made on page 82, et seq., with reference to the merits of trotting, apply equally well to ambling, with the exception that the equilibrium of the animal's body is not maintained as easily in it as in the
trot, which, consequently, is the less fatiguing pace to the horse. The amble is a natural pace of the camel.

The amble is, probably, a slightly faster pace than the trot; the apparent cause being that the equilibrium is more insecure (p. 54) in the former than in the latter.

Ordinary Walk.
The Walk.—This is a movement of four time, and is a pace in which all the limbs move, respectively, one after the other. If, for instance, the near fore leads, the sequence is: 1. near fore (Fig. 99), 2. off hind (Fig. 100), 3. off fore (Fig. 103), 4. near hind (Fig. 106). If the near hind begins, it will be 1. near hind, 2. near fore, 3. off hind, 4. off fore. Each foot comes after the one which precedes it, at an interval of about half the time occupied in taking one step. The result of this is that we have the following order of supports. 1. right pair (Fig. 98), 2. right diagonals (Fig. 101), 3. left pair (Fig. 103), 4. left diagonals (Fig. 106). As a rule, a horse begins the walk with a fore leg.

We may divide this pace into: (1) The short stepping walk, in which the prints of the hind feet do not come as far forward as those of the fore feet of their respective sides. (2) The ordinary walk, in which they more or less cover them. (3) The long striding walk, in which they go clear in front of them. (4) The high stepping walk, which is generally an artificial pace, and in which the feet are raised off the ground higher than usual. (5) The walk in heavy draught, which is a short stepping walk, and which has peculiarities that I shall presently consider.

Figs. 75 to 82 give an example of the ordinary walk; for the hind feet cover, as nearly as possible, the prints of the fore feet of their respective sides, and there is no exaggerated knee action.

The long striding walk is shown in Figs. 83 to 88. As an example of the high stepping walk, we may take the action of Napoleon's horse in Meissonier's great picture, "1814."

In the various forms of the walk—except in heavy draught on the level or up an ascent, or when going up an incline without having to pull a heavy weight—the healthy horse brings the heel of the foot first on the ground, or the flat of the foot. When the heel precedes the toe in touching the ground, the interval is so short that it is all but imperceptible. In cases suffering from certain diseases,
especially laminitis (fever of the feet), this interval is so well marked as to be characteristic of the ailment. In heavy draught which taxes the pulling powers of the horse (we have in Figs. 89 to 95 a representation of this pace), and particularly when going up a steep hill, the toe will be first brought down, as in Fig. 90. In Fig. 89, the right diagonals bear the weight of the horse. In Fig. 90 the near fore comes to their aid. There is a brief left support (Fig. 91). As the off fore is quitting the ground, the off hind comes down,
Fig. 89

Fig. 90

Fig. 91

Fig. 92

Fig. 93

Fig. 94

Fig. 95.

SHORT STEPPING WALK IN DRAUGHT
and continues its assistance while the weight becomes shifted on to the left diagonals (Fig. 93). After that, the weight falls on the right pair of limbs (Fig. 94), and again on the right diagonals (Fig. 95). In heavy draught, we may see that during the side supports there are never less than three feet on the ground, and sometimes even four. In the diagonal support, however, the two limbs may be alone on the ground for a brief period, or only very slightly assisted by the other legs. From this we may conclude that a fore and a hind limb work better together when they are diagonals, than when they are on the same side. This would support the assumption that the horse would work at the trot, other things being equal, with more mechanical advantage than at the amble.

In the representations of the walk, as shown in Figs. 89 to 95, and in Figs. 83 to 88, dotted lines are used to mark the positions of the toe of one of the fore feet, so as to compare it with that taken up by the toe of the hind foot of the same side. We see from this, that in the long striding walk, as depicted, the hind foot oversteps the print of the fore one, nearly as much as it fails to reach it in the walk during heavy draught.

Figs. 96 to 106 give a series from photographs of the normal walk. The movements of the off (or near) limbs, in Figs. 96, 97, 98, 99 and 100 correspond more or less accurately with those of the near (or off) limbs in, respectively, Figs. 101, 102, 103, 104 and 105.

The Canter.—The canter is, practically, a pace of three time, in which the footfalls are, for instance: (1) off hind (Figs. 107 and 114); (2) off fore and near hind (Fig. 109), or off fore followed after a very short interval by the near hind (Fig. 115); and (3) near fore (Figs. 110 and 116), which may or may not be followed by a period of suspension before the horse again brings down his off hind (Figs. 112 and 122). The fore leg of the diagonal support may come down a little before its hind fellow,

Phases of the ordinary walk of a high caste Arab (continued).
**THE CANTER**

**Fig. 107** Support on Off Hind (1st Time)  **Fig. 108**

**Fig. 109** Right Diagonal (2nd Time)  **Fig. 110**

**Fig. 111** Support on Near Fore (3rd Time)  **Fig. 112**

**Fig. 113**—Support on Off Hind (1st Time).

"Typical" Canter without Suspension.
as in Fig. 115. In the canter of the cart-horse shown in
Figs. 107 to 113, there is no period of suspension.

As an exceptional case, I may mention that the canter
of the riding school, when very short and greatly collected,
may be a pace of four time.

In the canter, the fore leg which does not belong to
the diagonal support is called the leading fore leg. If, as in
Figs. 107 to 122, it be the near fore, the movement is said
to be a canter to the left; if the off fore, as in Figs. 123
to 132, a canter to the right; the reason being that at
this pace, or at the gallop, the horse should lead with the
leg of the side to which he is being turned or circled. If
when leading with the off fore, for instance, he be turned to
the left, he will be liable to cross his legs and fall. I may
remark that in the gallop or canter, a horse can cross his
fore legs only with the leading leg. We may observe that
the hind leg which, in due rotation, alone supports the weight
of the body, is on the side opposite to the leading fore leg.
In the canter shown in Figs. 107 to 113—which, with or
without a period of suspension, is usually regarded as the
typical canter—the supports are the same as the footfalls.
In the one portrayed in Figs. 114 to 122, the diagonal support
(off fore and near hind, Figs. 115, 116, and 117) does not at
any time act unaided (as in the other form of canter, Fig.
109); but is assisted by the other hind leg and the other fore
leg in turn. This smooth style of canter might be termed
(to use a popular expression) a hand gallop. We may note
that when there is a period of suspension in the canter, and
also in the gallop, it is obtained by the fore hand being raised
by the straightening of the leading fore leg (and especially by
that of its fetlock joint), as it quits the ground (Figs. 118
to 120).

The time (three) of the movement shown in Figs. 114 to
122 is irregular; for the interval during which the suspension
takes place between the coming down of the near fore and
off hind, is longer than either of the other two intervals.
Supposing that the speed be the same, and that there be the
Ordinary Canter or "Hand Gallop."
same interval of suspension in an irregular canter of this kind and in a typical canter, the former would be less distressing to the horse than the latter; for the weight is better distributed in it. The same remarks apply to the canter shown in Figs. 123 to 132, which is a series, from photographs, of an easy canter of a high caste Arab, in which the near hind is on the ground when the left diagonals come down (Fig. 125), and they are supporting the body when the off fore reaches the ground (Fig. 127).

We see that, in the canter, the leading fore has more work to do than the non-leading fore leg. Hence, if this pace be long continued, the rider should, if possible, make the horse change the leading fore leg.

**The Gallop.**—This is a pace of four time, in which the feet follow one another in succession, with an interval of suspension between the coming down of the leading fore foot and that of the opposite hind foot (Figs. 133 to 148). If we compare that series with Figs. 107 to 113, and with Figs. 114 to 122, we shall see that, in the canter, the fore leg of the diagonal support comes to the ground at the same moment (Fig. 108) as, or slightly before (Fig. 115), its hind fellow; but, in the gallop, it comes after it (Figs. 135 to 137). We may note that this interval, in which consists the difference between the canter and gallop, is dependent on the extent of the forward reach of the non-leading fore leg. Hence we see that the canter merges imperceptibly into the gallop, and that the difference in these paces, in the same animal, is simply
Phases of the Hand Gallop of a High Caste Arab.

FAST GALLOP.
Fig. 141.  

Fig. 142.

Fig. 146.  

Fig. 147.  

Fig. 148.  

Fast Gallop (continued).
one of forward reach of fore leg—that is, of speed. I may mention that the intervals of time between each of these positions represented by Figs. 133 to 148 are all equal. We may see, starting with Fig. 133, that the near hind, off hind, near fore, and off fore (the leading fore leg) remain for nearly the same time on the ground. The leading fore, however, has to perform a longer period of support than any of the other three. It is also more extended when it touches the ground than is the non-leading fore leg, as we shall note if we compare Fig. 140 with Fig. 137. Hence it is more liable than the other limb to suffer from sprains of the suspensory ligament and check ligament (inferior carpal), both of which structures aid in supporting the fetlock joint. As regards the injurious effect of concussion, it would appear that the non-leading fore leg (Figs. 136 and 137), by reason of its coming to the ground at a moment when it is wholly unsupported by the other fore limb, would suffer more from concussion than the leading fore. Consequently, I venture to submit that, when the ligaments of the leading fore leg get sprained during the fast gallop, the cause is over-extension rather than the popular one of concussion, or even of sudden jerk. We may also see from Figs. 143 to 145, and from Figs. 130 to 132, how it happens that the back tendons (especially the flexor perforans) of the leading fore, during a gallop or canter in "heavy" ground, are far more apt to become sprained than those of the non-leading fore leg; for, immediately before the period of suspension, they have (on the contraction of their muscles) not only to help in raising the fore hand by the straightening of the fetlock (Fig. 144), but have also to overcome the resistance which the soil offers to the withdrawal of the foot from its surface.

In the fast gallop the horse has never, or perhaps only for a very brief period, more than two feet on the ground. At that pace, suspension is obtained more by "doubling up" the legs, than by raising the body off the ground.

A horse galloping at speed sometimes brings the toe of the advanced fore foot in front of the end of the muzzle, as we
may see in Muybridge’s admirable book, Animal Locomotion, vol. ix. Also, at this pace, the angle which the face, when viewed in profile, makes with the horizontal plane, more often exceeds than is less than 45°. I may say that, unless in very exceptional cases, it is never less than 40°. We have on rare occasions, in jumping, extreme extension of the neck.

**Passage.**—Having no more suitable term to express the artificial pace under consideration, I am forced to employ the French word *passage*, that signifies a short and very high trot, in which each fore limb, in its turn, when it is raised to its highest point, is poised in the air for an instant, and is bent at the knee and fetlock. It may be called the prelude to the *piaffer* (p. 79), and is an *air de manège* (high school pace). The “passage” of the English military riding school is a movement (*à deux pistes*) by which ground can be taken to the right or left without the rider being obliged to turn his horse. In Fig. 149, which shows the *passage*, the rider’s bridle hand is held high, so as to bring the animal’s neck in
a more or less vertical direction. When it is held in this position, the muscles of the neck will be in the best position for raising the fore limbs, alternately, high off the ground (p. 68).

**The Spanish Walk and Spanish Trot.**—These high school paces are, respectively, similar to the ordinary walk and trot, except that when each fore leg is advanced in its turn, it is poised for a moment, and is kept more or less straight out, and about as high as the elbow. Fig. 150 gives a representation of the Spanish trot. With respect to the position of the rider's bridle hand, see preceding paragraph.

**The Rein Back.**—The movement to the rear called the rein back may be executed at the walk or trot. The rein back at the walk or trot is performed in a reversed, though exactly similar, manner to the “short stepping walk,” or short trot to the front. The so-called *galop en arrière* of the high school is not a canter. It is merely a series of short jumps to the rear.
I wish to draw my readers' particular attention to the two different methods of backward propulsion adopted by the horse, when he makes this movement to the rear. (1) When he is at liberty, or when he reins back "collectedly" with a capable rider in the saddle, he lowers his head so as to put weight on the fore hand, and pushes himself back by the alternate straightening out of his fore legs; while the hind legs, being comparatively free of weight, are raised higher and with greater freedom than the front ones. It is evident that this high and light action of the hind limbs is as conducive to the safety of the rein back, as would be the same style of movement of the fore legs in paces of forward progression. (2) When the horse in harness tries to push a heavy weight to the rear, or when he "plants" his hind legs on the ground owing to unwillingness to rein back or to unskilful handling by his rider or driver, he will make his effort or his "defence," as the case may be, by throwing the weight on his hind-quarters. In the event of the centre of gravity of the horse (and of the rider) falling to the rear of the base of support (p. 46) formed by his four feet, he will, if in saddle, have to make a hurried and consequently a low step to the rear with one hind foot, which may be followed by the other feet in a more or less disorganised and insecure manner. If the hind feet fail to come quickly enough to the support of the centre of gravity, a fall will be the inevitable result. Besides the danger of this rein, or rather run, back, the fact of the hind limbs (which are far less suited to bearing weight than the fore ones) being surcharged with weight will render them liable to become injured, and will make this movement to the rear far more fatiguing to the animal than if it were executed in the manner first described. It behoves us, therefore, if we wish to rein back a horse which we are riding, to adopt the safer and less tiring method. With this object in view, when we wish to make a horse which we are riding, rein back, we should keep our hands "down," so as to allow him, or, if needed, to induce him, to lower his head and put weight on his fore hand. We should avoid the practice,
taught in English riding schools, of taking an equal pull on both reins; for, if we do so, we shall adopt the best means to induce the animal to throw his centre of gravity to the rear, and to adopt the second method of the rein back, which is objectionable in all cases, except in heavy draught. Instead of this "even feeling" on both reins, we may effect our purpose by, for instance, taking a stronger pull on the near rein, so as to bend the horse's head and neck more or less to the left, draw back the right leg, and touch him with it on the side. The weight then, on account of the head being turned to the left, will be placed more on the near limbs than on the off ones. Consequently, when the off flank is touched by the drawn-back right foot, the animal will, as a rule, readily lift up the off hind foot from the ground, and, feeling the backward pull of the near rein, his natural impulse will be to take a step to the rear with his off hind, and, in order to preserve the previous distribution of weight, he will follow it with his near fore. When the rider has obtained this diagonal step (with the near fore and off hind) to the rear, he can get the other diagonal step (with the off fore and near hind) by slackening the near rein, taking a pull with the off rein, drawing back the left foot, and touching the horse's left side with it; and so on. I need hardly say that, as each step is obtained, the drawn-back leg should be brought forward. I may also remark that a straight direction to the rear is maintained by the pressure of the drawn-back leg, whichever it may be at the time. We may see that the tendency of the well-broken horse, when reined back in this way, will be to adopt the diagonal movement (or trot) to the rear. Of all unhorsemanlike proceedings, the practice of "chucking" the animal in the mouth with the reins, to obtain the rein back, is one of the worst; for it will tend to make him, in his endeavour to escape the painful pressure of the bit (curb or snaffle), throw his weight to the rear, and run back according to the dangerous second method. Although the well "collected" rein back may be done at the walk or the trot, the rein back by the second method is never executed at the trot;
for the weight is too unequally distributed to admit of the simultaneous action of an off fore and a near hind, and of a near fore and an off hind. I need hardly say that the rein back in light harness may be similar to the rein back in saddle. When the object of the rein back is to push a great weight to the rear, as in heavy draught, the horse will have to exert his powers in bringing his centre of gravity as far back as possible. Consequently, he ought to have his head well
raised, and ought to get his hind feet under him as far as he can without slipping. In this he will be greatly assisted by having calkins on his hind shoes.

Foot-prints of the Horse during various Paces.—In the study of the foot-prints of the horse we are struck with two notable facts: (1) The faster the pace, the greater tendency has the hind foot to be placed beyond the fore foot.
of the same side. Here we have the influence of instability of equilibrium in increasing the speed (p. 54). (2) The faster the pace, the nearer do the foot-prints of all four feet tend to come into the line of direction in which locomotion takes place. As Lenoble du Teil expresses it, the foot-prints of the race-horse at full speed resemble the marks that would be made by the spokes of a wheel which had no felloes. This fact proves the undesirability, from a speed point of view, of any undue width between either the fore or hind legs (p. 53). In Figs. 151 to 158, for which I am indebted to Barrier and Lenoble du Teil, the left-hand dotted line of each diagram represents the direction of the prints of the near feet; and the right one, those of the off feet. In Figs. 151 and 154 the prints of both fore feet are covered by those of the hind feet. In Fig. 157 the prints of the near fore foot are covered by those of the near hind foot. In these figures only the succession of the foot-prints has been noted. No attempt has been made to mark the lateral distances between the respective lines of direction of the near and off feet.

The length of stride in the canter is about 12 feet; that of the full speed gallop of the race-horse, about 24 feet.
CHAPTER XIII.

LEAPING.

Definition of the Leap—Varieties of the Leap—Difference between the Horse's Leap and the Suspension of his Body during the Canter or Gallop—Manner in which the Horse takes off—Period of Stride at which the Take Off is effected—Effect of Pace and Speed on the Leap—Clearing a Fence—Landing over a Jump—Influence of Blood in Jumping.

Definition of the Leap.—The ordinary leap or jump is the projection of the body off the ground by means of the hind limbs, after the fore hand has been raised.

Varieties of the Leap.—We may divide the leap into the running jump and the standing jump; and each of them into the high leap and long leap, which are differences merely of degree.

Difference between the Horse's Leap and the Suspension of his Body during the Canter or Gallop.—In the leap, the period of suspension takes place when the hind legs quit the ground; in the canter or gallop, when the leading fore leg is raised (compare Figs. 195 to 199 and Figs. 186 to 190 with Figs. 130 to 132, and with Figs. 144 to 148). It is instructive to note that a definition founded on this difference is not of general application to other animals. In the gallop of the greyhound, there is a period of suspension (Figs. 162 to 164) similar to that of the horse's leap, as well as one (Figs. 159 to 161) like that in the horse's gallop. It seems that the former is longer than the latter in
the full speed gallop of the greyhound. It appears that if this dog begins his stride on one fore leg, the right for instance (Fig. 159), he will after his two periods of suspension (Figs. 160 and 163) "take off" from the opposite fore leg, the left (Fig. 165) in this case. If this be true, his stride

(counting it as the interval between the supports of the same leading fore leg) will include four periods of suspension. In the gallop of the cat (Figs. 166 to 171), and also in that of the tiger, panther, and cheetah, the leaping form of suspension
appears to be the only one present. I may mention that I have not had an opportunity of observing the paces of other large felines. The Indian black buck and the South African springbok, which are two remarkably fast kinds of antelope, generally begin their gallop by a series of leaps, when suddenly startled. The gallop of the mastiff (which is a comparatively slow dog), depicted by Figs. 172 to 177,

**GALLOP OF THE HEAVY DOG.**

resembles that of the horse. I may remark that the longer the period of suspension, the faster and more fatiguing, as a rule, will be the gallop.

Figs. 195 to 199 show photographs of the leap from taking off to landing.

**Manner in which the Horse takes off.**—In the canter or gallop, the animal makes his preparation when he supports his body on his leading fore leg (Figs. 178 and 181), by straightening which (and especially its fetlock joint) he raises his fore hand. At the same time, he brings one hind leg down (generally that on the same side as the leading fore), followed by the other hind (Figs. 179 and 180, and Figs. 183 and 184), and, by straightening them out, projects the body upward and forward (Figs. 185, 186 and 187). We may note that there is, practically,
no period of suspension (Figs. 178 and 179, and 182 and 183) between the removal from the ground of the fore leg that supported the weight, and the putting down of the hind leg which first comes on the ground.

From the halt, the horse would prepare to leap by making a rear (p. 75), and would project himself forwards and upwards when he had raised his fore hand sufficiently. From the walk, trot or amble, he would take off from either fore leg, and would bring the hind legs under the body as might be required.

**Fig. 178**

**Fig. 179**

"Take Off" of Leap, with Hind Feet not brought well under the Horse

**Fig. 180**

Period of Stride at which the Take Off is Effected.—In the running leap from the canter or gallop, we may regard the putting down of the leading fore leg (Fig. 181) as the commencement of the take off; for, at that instant, the character of the pace is changed, and the "take off" by the hind legs is made close to the foot-print of that leg. We therefore see that during the stride of, say, from four to
THE LEAP

The Horse's Leap.

Fig. 188.
seven yards in length, there is only one moment at which the "take off" can be executed. Hence, if a horse does not regulate the length of his stride when coming up to a fence, he may easily make a mistake. Let us suppose that, while taking a stride of five yards, he brings down his leading fore leg three yards short of the proper spot at which he ought to take off; he will then have to jump three yards "bigger," or chance an accident by taking off two yards too near. The longer the stride, the greater will be the tendency to this error. Consequently, other things being
Phases of the Leap.

Fig. 195.

Fig. 196.

To face p. 110.
equal, a short-striding horse will be safer over a "cramped" country than a long-striding one. Also, we may say that no horse merits the title of "a safe conveyance" unless, when coming up to a jump, he accurately regulates the length of his stride, and "puts a short stride in," when required.

In the trot or amble, the putting down of the fore foot, which is the last to quit the ground, may be looked upon as the beginning of the take off.

**Effect of Pace and Speed on the Leap.**—The running jump is usually executed at the canter or gallop. A few horses can leap (especially height) cleverly from the trot, which is a useful accomplishment in the hunter; for it may enable him when in a difficult position (as when jumping out of a lane) to utilise a "run" which would be too short for the longer stride of the canter or gallop. Besides, at these paces there is only one period of the stride at which the animal can take off (see preceding paragraph); but in the trot there are two such periods, namely, when the respective diagonals come to the ground. A horse, however, cannot jump so freely and "big" from the trot as from the canter or gallop, in each stride of which, the hind legs are brought nearly together under the horse's body (Figs. 130 and 143), ready, if need be, to change the pace into the leap (Fig. 178). In the trot, each hind limb moves harmoniously with its diagonal fore leg; but in the opposite direction to its hind fellow.

In examining the various kinds of leap of the horse, we must remember that he has a long distance (that from his hocks or buttocks to his muzzle) of body to carry over a fence, independently of raising it to a sufficient height; hence his high jump partakes much more of the long jump than the high jump of a man, whose body is carried more vertically than horizontally. For this reason, it is more essential for a horse than for a man to "get up" a fair degree of speed in order to jump height well.

The speed at which a horse goes at a jump (supposing
that it does not prevent him from "collecting" himself properly), influences the width he can clear; because (as we have seen on p. 49) the force by which he is projected forward into the air is equal to the force of propulsion derived from his limbs, plus the impetus due to the speed at which he is going. The greater this impetus, the lower will be the "angle of elevation" at which the centre of gravity of the body is propelled forward.

We may, with approximate accuracy, define the "angle of elevation" as the angle which a line passing through the centre of gravity and a point midway between the prints of the two hind feet, makes with the horizontal plane, at the moment when the body leaves the ground.

Looking at the subject from a hasty point of view, those of us who have not had practical experience, might come to the conclusion that a horse would jump height as well when going fast as when going slow, and that the only difference is that, in the former case, the animal would be obliged to take off further from the fence than in the latter. This supposition, however, does not hold good; for the faster the pace, the more weight is thrown on the fore hand, and the greater difficulty will the leading fore leg have in raising the fore hand off the ground. Hence, even without the valuable experience of the hunting field and steeplechase course, we may accept the truth of the old saying that one should ride slow at "timber." Also, I am inclined to think that a horse will not clear as great a width when taking a water jump if he is sent at his topmost speed at it, as he would do were his rate of going slightly moderated, so as to enable him to raise his fore hand sufficiently off the ground in order to obtain the angle of elevation which will enable him to cover the maximum distance.

**Clearing a Fence.**—It is evident that the more a horse, in the leap, brings his hind feet forward as compared to the position of the prints of the fore feet, the greater
Phases of the Leap (continued).
CLEARING A FENCE.

will be the angle at which he can, at the speed he is going, project his body upward. Also, the more he raises his head, the more will he, by bringing back the centre of gravity, increase its angle of elevation. Besides, as the forward and upward movements of the fore limbs depend on the action of the muscles of the neck, the direction in which the fore legs will be raised, will naturally depend on that of the neck. A horse, therefore, when approaching a fence which will tax his powers to clear, should regulate his speed, so that the impetus obtained from it may be in due proportion to the propulsion derived from the limbs, should bring his hind feet well under his body; and should hold his head high. I am here supposing that the animal takes off at the correct distance from the obstacle. These actions constitute, as regards the horse, what is popularly and somewhat vaguely called "collecting" himself.

We may note that although, when preparing to leap, the hind legs are brought down on the ground in a straightened out position (see the off hind in Figs. 179 and 184), and leave it in the same attitude (Fig. 186), they are somewhat bent at the hocks and stifles (Fig. 185) at a time intermediate to these two moments. Hence, we see from these drawings that the propulsion from the hind legs in the leap is due to their being suddenly straightened out, in which action, the fetlock joint also plays an important part.

As the ability to clear height depends greatly on the power of raising the fore hand; the rider should refrain from leaning forward when the horse is rising at an obstacle. He should, on the contrary, if anything, lean back at this moment (Fig. 195), so as not to put any avoidable weight on the fore hand.

In almost all cases of the well executed high jump, the fore legs are bent up together and the hind ones fully straightened out at the moment of taking off (Fig. 200). The fore legs will be kept more or less in this position till
the fence be cleared. If the obstacle be "stiff" and the horse hit it with his knee or fore arm, he will probably fall; but if any part of the leg below the knee strike it, he will generally get over all right, or with a "peck" at most. Hence, a clever horse will try to avoid an accident by raising his knees well out of harm's way. Another danger consists in the horse catching the fence with his hind legs, which he will best avoid by bending them as much as possible at the stifles and hocks (Fig. 203). Consequently, the clever jumper, the moment his hind legs quit the ground when taking off, will tuck them under him as if they were on springs suddenly let go, after having been drawn out. The slovenly fencer, on the contrary, will drag his hind legs after him, at the imminent risk of catching them in the fence and falling. In the high jump, the animal should keep his hind legs well bent until he is clear of the obstacle (Fig. 206), so that, if need be, as might occur in the case of an unexpected wide drain being met with at the landing side, he may strike the fence with his hind legs, and thus give himself a fresh forward impulse.

When a horse is suspended in the air during a leap, he may move his limbs or retain them in one position, according to what he feels to be most conducive to his safety.

Landing over a Jump.—The prettiest style, and safest manner, of landing in the leap, is for the two fore legs to be kept straightened out and comparatively close together (Figs. 198 and 199, and 201 and 202) until they are near the ground, when one of them comes down, and is followed by the other, which is placed a little distance in front of it. This method of landing gives the impression to the observer that the horse comes down on both fore feet at the same time. If we compare these figures with Fig. 189, we shall feel convinced that the plan of landing with one fore leg considerably bent, as in the latter style, is not so safe as in the former; for in the event of any falter being made by the supporting fore leg, the other fore leg will be better prepared to save the
Fig. 200.—Cloister and Horizon jumping open ditch at Sandown Park.
horse from a fall, if at that moment it be straightened out, and not bent.

It is evident that, for safety, the knee of the leg upon which the animal lands, should be as straight as possible, for if the knee "gives," the horse will almost certainly fall. Hence, we may regard the condition of being "over at the knees" (p. 193) as a grave defect in the jumper, especially if he be required to go fast.

As a rule, when landing over a jump, the hind foot which first comes down, has been made way for by the fore foot of the same side, somewhat beyond the print of which it is placed. The other hind foot and the other fore foot act in a similar manner. We may see from Figs. 190 to 194, that a horse "gets quickly away from a jump" by the raising of the fore hand, which is accomplished by the straightening out of the fore limbs. The rider should, therefore, avoid throwing any undue weight on the fore hand at this moment. It sometimes happens that a horse "over-reaches" (strikes a fore leg with a hind foot) when landing over a jump on account of the rider being jerked on to the animal's neck; the injured fore leg having been prevented from getting out of the way of its hind fellow by the surcharge of the fore hand. The heavier the fore hand, other things being equal, the further forward, when landing over a jump, will the hind feet be carried as compared to the fore feet; and vice versa. Hence, the faster the pace, the greater will be the tendency to over-reach. We see this to be especially the case in
jumping water, at which, not alone is the speed as a rule high, but the ground on landing is often soft and "holding" from the infiltration of water. It is evident that the "deeper" is the ground, the more difficult it will be for a horse to extricate his fore feet out of it in time to make way for his hind feet. We may see therefore the advisability in such cases of leaning well back in the saddle. Figs. 209, 210, and 211 show consecutive movements of the horse after landing over a jump.

A horse should not land with his head and neck bent, as might be caused by the action of a severe bit which he is afraid to "face"; for when the neck is bent, the muscles* which draw the fore legs forward and enable them to reach well to the front, will be more or less thrown out of action. Hence, the rider ought to give the horse plenty of rein on landing, and should try to avoid bringing his weight forward. As an interesting point in the action of a severe bit in leaping, I may mention that if we observe a horse that is being ridden up to a high jump in a bit which he is afraid to "face," he will land, in the event of his clearing the obstacle, more or less on all four legs at the same time, in his endeavour to save his mouth from any sudden "job," by keeping the weight as much as he can off his fore hand. He may act in the same way, even with a snaffle, if too short a martingale be used. I may remark that the two "defences" which a horse generally uses against a severe bit, are to poke his nose up in the air, and to draw his chin in towards his chest, and thereby arch his neck. Many persons, against the evidence of photography, assert that a clever jumper will generally land first on his hind legs, and will then (so they say) be in the best position to "get away" quickly. They quite forget (or perhaps do not know) that the hind limbs of the horse are altogether unfitted to stand the violent shock which would be

* The chief of these muscles is the *levator humeri*, which is attached to the top of the head and to the upper third of the humerus. The nearer its points of attachment are brought together, the less power has it to draw the limb forward.

transmitted through them, if they had to bear the weight of the body on landing. Such poor weight-bearers are they, that they have great difficulty, as a rule, in enabling a horse to walk a few yards on his hind legs. Almost all circus horses which have to perform this trick, throw out, after a short time, curbs, spavins and thoroughpens of amazing size. What, I wonder, would be the state of the hocks of a hunter or chaser, had he always to land first on his hind legs! The fore limbs, on the contrary, being attached to the body only by muscles, are singularly well adapted to support shock, like that of landing over a fence. Besides, if a horse, which, like all other animals, is obliged to "take off" from his hind legs, were, also, to land on them, he would lose all the advantage which the forward reach of his fore legs gives him. As we have already seen, a horse in the gallop, after the period of suspension, lands on a hind leg; but in the leap, he lands on a fore leg.

In the well executed leap, the fact of the horse landing on one fore leg and then on the other, lengthens the base of support, and thus increases the stability. The hind legs coming down in the same manner enables the horse to at once take up the gallop, which is in four periods, without loss of time (Fig. 194). The safest way for a man, on the contrary, to alight is on both feet kept together, with the knees somewhat flexed (Fig. 35), in order to break the shock of concussion; for his body is placed vertically, and not horizontally, as is the case with the horse. In drawing any comparison of this kind, we must remember that our legs are attached to the trunk by bony union, at our hip joints, and not, as in the fore legs of the horse, by muscles which act as springs in nullifying any injurious effect from the force of impact with the ground. Again, in the horse, although the knees must be kept straight, on landing, in order to insure stability; the fetlock, elbow and shoulder joints act as springs. As man is a plantigrade animal (one that walks on his hocks; p. 27), he must utilise the "play" of the knee-joints, with which to break the force of concussion, when he lands on the ground with any great
If, in such a case, the knees be kept straight, the shock will fall in its entirety on the pelvis, at the hip joints, and may be transmitted with very serious effect to the spinal cord. Men who practise hurdle-racing on foot, alight on one foot, and then bound off on to the other; as their great object is to lose no time in getting away from their fences, which, being comparatively low, do not greatly affect the athlete's stability.

We may see from the foregoing considerations, that for safety and quickness in "getting away" after a leap, it is essential for the fore legs to be removed out of the way of the hind feet, and for the fore hand, which was previously depressed by the weight of the body falling on it (as in Fig. 189), to be raised by the straightening of the fore legs (Figs. 190 to 194). These two actions, I need hardly say, have to be performed with speed and precision. Hence, it is necessary for the horse to see where he is going to place his feet on landing; so that he may be prepared for the required movements of the limbs. If he be prevented from knowing when his feet will come down on the ground, there will be loss of time in calling the muscles of the limbs into action, and the probability of an accident will be greatly increased. A common way some riders have of making a horse, when jumping, fall or over-reach in this manner, is to "throw up their hands," and thus cause the animal to unduly raise and extend his head, which he does with the object of "saving" his mouth; the result being that the horse cannot accurately see where he is going to put his feet. The rider, on the contrary, should keep his hands low and should give his mount plenty of rein, so as not to interfere with the animal's movements when landing.

**Influence of Blood in Jumping.**—Seeing the manner in which the rate of speed influences the extent of the long jump, we may reasonably conclude that a fast galloper, other things being equal, would jump a greater width than a slow horse. The possession of great galloping speed, however, would not,
Getting away after Landing.
of itself, materially assist the high jumper. I regret to say that I have no exact data to go on; but my own experience leads me to conclude that the majority of big water jumpers will be found among well-bred horses. As the height or distance over which the body is propelled by the limbs depends on the speed at which they are straightened out; we shall find that a horse which is quick in his movements, other things being equal, will jump higher and broader than another which is slower. For this reason, the thoroughbred, properly selected and trained, will make the best of all jumpers, over height as well as over length.
CHAPTER XIV.

NOTATION OF THE PACES OF THE HORSE.

That distinguished French savant, M. Marey, published in 1878 his researches on the paces of the horse. He prosecuted them by means of a registering apparatus somewhat similar to the one, the sphygmograph, used by doctors for recording the movements of the pulse. The machine consisted of a cylinder which was made to revolve round by clockwork. Attached to it were four pointed levers that were arranged so as, when pressed upon, to trace lines on a piece of blackened paper. Each of these levers was supplied with an india-rubber tube, which communicated with a rubber ball filled with air and fixed on the ground surface of one of the animal's feet. These levers and their connections were made so that, when the horse during movement put a foot on the ground, the rubber ball attached to that particular foot would be compressed, and the air rushes into the tube would raise the lever and bring its point against the sheet of blackened paper. When the animal lifted its foot from the ground, the air would go back into the ball, and allow the point of the lever to be taken off the surface of the paper. As, while this was being done, the cylinder revolved round at a uniform rate of speed, it follows that the line traced by each lever point would be a record of the duration of the contact of the foot with the ground, and that the intervals between two such contacts would be a measure of the time the foot was suspended in the air. By this means, Marey investigated the nature of the paces of the horse. He also devised a very ingenious method of representing them on paper, which I shall now try to explain to my readers.

If we wish to express on paper the running pace of a man, we may do so by making a scale with rectangles, which, for convenience' sake, we may use instead of Marey's lines. Thus, if the time of contact be about equal to that of suspension, Fig. 212 will express the nature of the pace. To render this figure more graphic, I have used plain rectangles to mark the supports of the left foot, and shaded ones, those of the right foot. If we desire to represent the ordinary walk of a man in the same manner, we shall be confronted with the difficulty that, as both feet are on the ground at certain periods of this pace, the rectangles would naturally have to overlap each other. We may, however, get over it by placing the diagrammatic prints of, say, the left foot on a line above those of the right foot. In this manner, in
NOTATION OF THE PACES OF THE HORSE.

order to represent the run, we would place these footprints as they are shown in Fig. 213; not as in Fig. 212. We may indicate the walk by Fig. 214, in which I have assumed that both feet are on the ground for one-sixth of the period of support of each foot.

We must remember that these scales or notations give us only the order of succession of the feet, and their respective and proportionate periods of support and suspension; but they do not furnish us with a clue to the speed of any particular pace, except that, when there is a period of suspension, the longer it is, the greater, as a rule, will be the speed.

To construct the respective notation of the various paces of the horse, we may employ the rectangles of Fig. 212 for the fore legs, and may use similar ones, placed underneath them, for the hind legs. Thus, Fig. 216 will give us the scale of the trot as shown by Figs. 55 to 58.

My readers will notice that the dotted lines on Fig. 217 mark the respective moments at which the horse assumed the positions depicted in Figs. 59 to 63. In the remaining notations in this chapter I have similarly marked the connections between these scales and the corresponding figures in Chapters XII. and XIII.
CHAPTER XV.

COMPARATIVE SHAPE OF HORSES.

General Remarks—Relations between Height and Length of Body—Comparative Height at Withers and Croup—Points in Common—Limit of Height—Thickness of Limb—Length of Neck—Length of Head—Width between the Foie Legs—Comparative Weight of Body—Comparative Length of the Bones of the Limbs—Differences of Conformation between the Two Sexes.

General Remarks.—In order to simplify comparison and to prevent tedious repetition, I venture to divide horses, from a conformation point of view, into (1) horses of speed, and (2) horses of strength; and also into (a) saddle horses, and (b) harness horses. Thus, we have the speedy saddle horse in the flat-racer; the speedy harness horse in the match-trotter; the strong saddle horse in the weight-carrying hunter and trooper; and the strong draught horse in the Shire or Clydesdale. I shall therefore contrast, in this chapter, "points" of speed with those of strength; and the differences between horses intended for the saddle, and those required for work in the shafts. English and Colonial lovers of horses will demand a further distinction—to which I shall do my best to attend—between flat race horses and cross country horses. In general terms, the outcome of this research will be a more or less successful investigation into the "points" of the race-horse; hunter, trooper, or riding hack; match trotter; light harness horse; and heavy cart-horse. I shall endeavour to show later on, that all riding hacks and cavalry horses should possess the jumping points of the hunter. It is evident that the steeplechase horse should be a judicious combination of the hunter and the race-horse. The fast horse, whether racer or American match trotter, can no more
dispense with a certain amount of strength than can the heavy draught horse attain excellence without a certain amount of speed, even at the walk. I need hardly say that the light vanner belongs to a class intermediate between the light harness horse and the heavy draught horse.

The method of working from the whole to a part should be followed as rigorously in judging a horse, as in painting or land surveying. If we desire to obtain correctness in these arts, we must, as a rule, first get our general outline, and then fill in the details. If, in our preliminary examination, we allow our eyes to be caught by some isolated beauty or defect, we would be—to use an oft applied simile—like a painter who begins a full-length portrait of a person by drawing the nose, and then hangs the remainder of the body to it. I cannot too strongly insist on the fact that the degree of adaptability of an animal for any special kind of useful work, depends more on his general “shape,” than on the possession or absence of any particular “point.”

I may mention that, in making comparisons, we should not be disconcerted by the fact that some of the proportions of the horse may vary a little according to the position in which he stands, and the nature of his bodily condition. Some allowance has to be made for the fact, in my illustrations, that the majority of the fast horses and jumpers were taken when they were in hard training; and most of the heavier horses, when they were in a “lingry” state. It would have been more satisfactory, if they had been photographed at a time when they were all in “hard” condition; but that, obviously, was out of my power to get done. The method I shall indicate will, however, give results sufficiently uniform for our purpose. We must also remember that the respective proportions of animals of the same class and of equal merit are not always the same, for a defect in one point may be compensated by increased excellence in another point.

**Relations between Height and Length of Body.**—
We have seen, in Chapter I., that the fundamental difference
between animals of speed and those of strength is that the former have comparatively long legs, and that the latter have comparatively short ones. We have in the camel a well-marked exception to this rule. The Ship of the Desert, as we may see in Fig. 228, has very long legs in comparison to his length of body, and yet he is extremely slow for his size. The cause of his lack of speed is chiefly owing to the weakness of his "rearing muscles" (p. 52), and to the straightness of the column of bones of his fore limb (p. 50). Hence, when he tries to go quickly, he is unable to raise his fore hand sufficiently to obtain a well-regulated period of suspension, like that of the horse (Figs. 62, 131, and 145). His gallop, which he attempts only on rare occasions, has so much up and down motion in it that he can continue it but for a very short time. His usual fast pace is a kind of amble which has no period of suspension. The muscles of his limbs, as compared to the weight of his body, are very poorly developed. Many "weedy" horses (p. 239) which have long legs are deficient in speed from causes similar to those that render the camel slow. The law as to length of limb can be amply verified, other things being equal,
in the case of the horse, by the hard logic of statistics. I accordingly give the following table of measurements in inches, taking Ormonde (Frontispiece) and St. Simon (Figs. 9 and 229) as examples of the fleet of foot, and the Shire horse, Cheadle Jumbo, and the Shire mare, Chance (Fig. 232), as illustrations of strength.

* Without shoes.

I took the measurements of Ormonde on the 20th July, 1887, when he was a four-year-old; and those of St. Simon in September, 1884, when he was a three-year-old. I may mention that the photographs of Ormonde and St. Simon are particularly valuable, as these animals were probably the two best race-horses that have ever lived, and as their photographs were taken when they were in racing condition. I may also mention that the outlines of Fig. 229 have been taken from a photograph which was too much “fogged” to bear reproduction. The shadows, however, have been added by an artist, Mr. Oswald Brown.

We see from the foregoing table, that some three and four year-old race-horses of the best class are 3 or 4 inches higher at the withers (and at the croup) than they are long in the body; and that the Shire horse, which is the most powerful of all horses, is about 9 inches longer than he is high. The difference between the two types with respect to their length of leg, as compared to their depth of chest, is
equally well marked. The intermediate classes, in this respect, partake, as a rule, of the characteristics of the respective types to which they are most nearly allied. Thus, if we take Ormonde (Frontispiece) as the highest type of the race-horse, we shall find that the distance from the top of his withers to his brisket, if applied down his fore leg, will reach from his brisket only to the bottom of his fetlock. In the high-class Leicestershire hunter (Fig. 329) it will come down to the middle of the pastern, in the heavy-weight hunter, to the coronet, in the Artillery "wheeler" or light cart-horse, to the ground; and in a Cheadle Jumbo, it will be four inches more in length. Hence we may conclude that the term, "short on the leg," is one to denote the possession of strength rather than of speed. The reckless manner in which it is used with respect to race-horses is as incorrect as it is ridiculous. I may add, that with age, good feeding and want of exercise, a horse usually lengthens, deepens, and thickens somewhat as regards his height. Mr W. F. Shaw, F.R.C.V.S., who has charge of the horses belonging to the London Streets Tramway Company, tells me that he has frequently observed that comparatively light, well-bred horses, when put to tramway work at about five years of age, thicken and get coarse after a few months, to a far greater extent than if they had been used at fast paces. I need hardly say that labour between the rails is slow; and the feeding (eighteen pounds of corn and twelve pounds of hay) ample for these not very large animals. We may accept the fact that both muscles and bones accommodate themselves in time to the nature of the work to which they are put; the difference being one of thickness, and not of length. I have often noticed among thoroughbreds that, to a certain extent, they became coarse and lost their appearance of blood if kept under rough conditions and used for ordinary hack work.

I may mention that St. Gatien, the celebrated son of The Rover and St. Editha, who ran a dead heat with Harvester for the Derby of 1884, won the gold cup at Ascot and the Cesarewitch (carrying the unprecedented weight of eight
Fig. 338.—Cleveland Stallion, Luck's All, the property of Mr. H. C. Stephens, M.P.

Fig. 339.—Cleveland Mare, Madam, the property of Mr. H. C. Stephens, M.P.
stone ten pounds for a colt of his age) in the same year, was
a very deep-chested horse, as his depth from his withers to
his brisket (just behind the elbow) was an inch more than
from his brisket to the bottom of his fetlock. He was thus
an inch deeper than Ormonde, who was one and three-quarter
inches deeper than St. Simon. St. Gatien, I need hardly
say, was particularly distinguished by his ability to stay a
distance.

The fact of foals (Fig. 233) being extremely “long on the
leg” accounts for their great speed as compared to their
strength. Without this peculiarity of conformation, there is
no doubt that the horse, prior to the time at which he
became domesticated, would not have survived the struggle
of existence

Comparative Height at Withers and Croup.—
“Comparative length of fore and hind limbs” would be a
more correct heading for this paragraph than the present one,
which I adopt solely for the sake of convenience. It goes
almost without saying that it is much easier to compare the
respective heights of a horse at the withers and croup, when
he is standing in the ordinary position in which we get him
placed for inspection, than to judge of the comparative
lengths of his fore and hind legs, clothed as they are with
skin and muscle. In adopting the more convenient method
of the two, due allowance should be made for the attitude
in which the horse places himself.

The conditions under which the limbs play their part
in locomotion, are so complex and varied, that I can lay
down rules on this subject only in very general terms. We
must also bear in mind that there is a certain limit of height
(largely influenced by breed) which the horse should not
exceed, and which will be discussed on page 134, et seq.
I may state the present question as follows: at any given
height, is it advantageous for the horse to be higher at the
withers than he is over the top of the croup, or vice versa,
when he is intended for galloping, jumping, light harness, or
heavy draught; and to what extent may such difference, if any, amount to? It is evident that the longer the hind leg, the greater—other things being equal—will be the speed of propulsion. Excess of height at the croup will, however, be accompanied by three serious drawbacks: (1) by putting increased work, during fast paces, on the fore limb (p. 51) and on the muscles of the back and loins (p. 52) in raising the fore hand at each stride, it will diminish the animal’s staying power; (2) by surcharging the fore legs (p. 40), it will naturally tend to render these limbs more liable to the injurious effects of work than they would be, were the weight more equally distributed between the fore and hind extremities; and (3) by overloading the fore hand, it will militate against the cross-country horse rising easily at his fences and getting away safely from them on landing. Those speedy animals, the cheetah, the Indian black buck, and the greyhound, are a little longer in the hind limb than they are in front. As a rule, race-horses of the highest class are about the same height at withers and croup. This difference between the racer and the other gallopers may be accounted for by the fact, that the proportion of weight which the fore limbs of the race-horse have to carry, is still more increased by the presence of a jockey on his back. Among the fleet of foot, I purposely omitted mentioning the hare, whose fine speed can be maintained, as we might have inferred, only for a short distance on level ground; though it is particularly hard to catch up a hill, the difficulty of ascending which is directly lessened by the fact of the fore limbs being shorter than the hind ones. Any disadvantage, in progression, arising from undue shortness of fore legs is, more or less, compensated for, in the hare, by great development of the muscles of the loins (“rearing muscles,” p. 52). The lynx (Fig. 4), which is very high behind, has an extraordinary turn of speed; but only for a short distance. Its gallop, like that of other cats, is a series of leaps (p. 106). From practical observations, I do not think that it is an advantage for a race-horse to be higher over the croup than at the withers.
C. Reid, Wishaw.

Dixon & Sons.

Fig. 232.—Mr. A. B. Freeman-Mitford's Shire Mare, Chance.
With regard to this point, we may study Ormonde (Frontispiece) and Persimmon (Fig. 322). Could a horse be reserved for races up-hill, like on the old Cambridgeshire course, which finished at “the top of the town,” increased height at the withers might be an advantage; but such a policy would hardly be practicable. We may conclude from the foregoing remarks, that if a race-horse be higher over the croup than at the withers, he will require, all the more, to have sloping shoulders, oblique pasterns and powerful loins, and to be light in his head, neck and shoulders.

We have now to consider the very practical question—which, no doubt, every man who goes in for pony racing has asked himself—is it an advantage for a pony which has to pass the standard at a certain height, to be considerably higher over the croup than at the withers? The results of my experience make me reply “no” to this query. The statement, which I have often heard urged, that a pony which measures, say, 14.3 over the croup, and which can pass the standard at fourteen hands, must have a “pull” over others of its own class which are as high at their withers as over their croup, is not borne out in practice. The best racing ponies I have seen, had no great difference between these two measurements—certainly not more than two inches. Among this list I may mention: the English ponies, Predominant (Fig. 236), Lord Clyde, Water-lily (Fig. 332), Maythorne, Mike (Fig. 235), St. Helena, Selena, and Sylvia, the New Zealanders, Little Wonder and Parekaretu; the Australians, Mayflower, Achievement, Chester, Bob, and Jeannette; the Arabs, Caliph, Little Hercules, Blitz (Fig. 370), and Sweet William; the Barb, Kangaroo; the Indian country-breds, Ruby, Bonnie Doo, and Daphne; and the South African, Coachman. Skittles, who belonged to Captain Mowbray of the Black Watch, and who was a very good fourteen hand pony, showed, I think, the maximum of comparative height behind. Her excess of height at the croup (about 2 inches) was compensated for by the possession of remarkably long and sloping shoulders. The large majority of racing
ponies I have known which were much lower at the withers than at the croup, stood work badly owing to their fore legs being unusually liable to become infirm. I think we may accept the statement that instability of equilibrium (p. 54), which is increased according as the weight on the fore legs exceeds that on the hind ones, should be obtained, in the galloper, more by the body being short and the legs and neck long, than by the difference of height between the withers and the croup. I cannot too strongly direct the attention of my readers to the necessity of the hunter (p. 245) being "light in front," and consequently being higher at the withers than over the croup.

The lower a horse is in front, other things being equal, the rougher will be his paces; hence an animal of this kind of conformation will not, as a rule, make a pleasant hack.

With the harness horse in movement on level ground and especially when going up an incline, the position of the burden will more or less diminish the instability of equilibrium, and consequently the speed: a proof of which statement is obtained from the fact that, as a rule, horses will trot faster under saddle than in a sulky. Also, we find that in match trotting, the tendency is to get the weight of the driver as far forward as possible. I believe I am correct in saying that, agreeably to these principles, the American match trotter is lower at the withers, as compared to his height at the croup, than the race-horse.

The heavy cart-horse, viewed from a purely draught point of view, ought to be higher in front than behind (p. 61).

Points in Common.—We may advance a step further in our search after the true principles of horse conformation; for if we compare the proportions of the body of the racer with those of the heavy draught animal, we shall find that they are essentially the same, and that the only real difference which exists between these two classes is in the length of
Sir Walter Gilbey's Shire Horse, Norman Conqueror, and Shetland Pony, Good Friday.
their legs. Were those of Ormonde, as he is in the Frontispiece, cut down nine or ten inches and proportionately thickened, and were he swelled out by "bulky" food, he would pass fairly well as a cart-horse! The statement which I have just made concerning the comparative proportions of the two extreme types of horses, may not appear so outrageous as it might do at first glance, if we consider that the difference of work between them is one of limbs and not of body. The galloper needs the highest possible development of speed with a sufficiency of strength; the cart-horse, a maximum of strength with a very moderate amount of speed; both the strength and speed being derived from the muscles of the limbs. The two classes, however, are in their work equally dependent on the organs (those of breathing, circulation, digestion, secretion, etc.) which are contained in the body. The lungs of the draught animal, when facing a stiff hill with a heavy load behind him, have to be in as good order as those of a racer who is finishing in front of the Grand Stand at Epsom or Newmarket. His stomach, bowels, liver, spleen, kidneys, etc., will also require to be as healthy as those of the other. Hence we need not expect to find, nor shall we meet with, any material difference in the proportions of the respective bodies of these two animals. If we take from the table given on page 127, the depths (from withers to brisket) of the four representative horses, and divide them respectively into the lengths of these animals, we shall find the ratio for Ormonde, St. Simon and Cheadle Jumbo to be 1 to 2.1, and for Chance, 1 to 2.2; while the ratio of their depths at the lowest point of their backs to their lengths will be in all four cases, 1 to 2½ (nearly). This is sufficient to prove the close identity of proportions between the depth and length of body both in racers and heavy cart-horses, and a fortiori with those of the intermediate classes, such as hunters, troopers, and light harness horses.

It may be objected to the foregoing remarks that, in the heavy draught animal, the shoulders are thicker, and the breast broader in proportion to the length of the body, than
in the case of the galloper. To this I may reply that the
difference is due, not to the shape of the body, but to the
size of the muscles which attach the limbs to the body, and
which consequently partake of the massive character of the
legs. We must also remember that the pelvis is a portion of
the hind limb (p. 26).

Limit of Height.—In all species of animals there appears
to be a limit of height which the respective members cannot,
as a rule, exceed, and at the same time retain strength, activity
and symmetry of form. We see this law well exemplified
in dogs, which can rarely surpass, say, thirty-four inches in
height, without becoming weak in the loins and clumsy in their
movements. For cart-horses, I shall put this limit at, say,
seventeen hands two inches; and for race-horses at, say, six-
ten hands three inches. Besides this maximum, there is a
certain height which it is no benefit for a horse, from a useful
point of view, to exceed. Although, to employ an old saying,
"a good big one will beat a good little one;" it is no
advantage for a racer, chaser, hunter, hack or light trapper
to be more than fifteen hands three inches, or a heavy cart-
horse to be higher than sixteen hands three inches. It is
an interesting fact that this standard of useful height varies
considerably in different breeds. I would put it approxi-
mately as follows:—English, North American, Australian,
and New Zealand thorough-bred and half-bred horses, fifteen
hands three inches; ordinary South African horses, fifteen
hands; Arabs, fourteen hands two inches; East Indians
(country bred, without admixture of English blood) and
Basuto ponies, fourteen hands; Mongolian, Yarkundi, Spiti
and Bhootiah ponies, thirteen hands two inches; Baluchi,
Herati and Cabuli horses, fourteen hands two inches; Burma
and Deli ponies, thirteen hands; Manipuri ponies, twelve
hands. On Indian race-courses it has been proved, times out
of number, that an Arab of fourteen hands two inches is as
good as any other son of the desert, no matter how much he
may exceed that height. In fact, there have not been many
Fig. 235. Colonel Simpson's English Racing Pony, Mike.

Fig. 236. H.H. The Maharaja of Kooch Behar's Racing Pony, Predominant, by Balfe, out of Dominante.
Arabs which have gone to India that were better than the gallant little Chieftain, who was only fourteen hands high, and who was the best of his time. The records of the Shanghai and Hongkong races prove that a good Mongolian of thirteen hands two inches (like Teen Kwang, see Fig. 350, who was the Eclipse of the Celestial Empire) can hold his own with any of his class, even at level weights. In China an allowance of only three pounds for an inch in height is given, and yet the best ones are found at about thirteen hands two inches. In India, on the contrary, an allowance of twelve pounds an inch is given; but, with very rare exceptions, a thirteen hands one inch or a thirteen hands two inch English, Australian, Arab or "country-bred" has no chance with a fourteen-hander of its own class. These striking differences in the standard of useful heights are no doubt chiefly due to the effects of climate; for if foreign blood be introduced into any country, it will, in a very few generations, assume the characteristics of the local type of horse or pony.

Careful selection in breeding, good feeding, and healthy conditions of life have a great influence in tending to increase the size, not only of individuals, but also of breeds, in which case the standard of useful height will naturally become raised. Thus the average English horse is, at the present day, probably six inches taller than he was 200 years ago. From my own observation, I am inclined to think that horses in England have increased about an inch in height during the last thirty years. We should remember that when we refer to certain breeds of ponies, we allude to horses that have for generations been kept small by privation, inclemency of climate, or other influences which have retarded their growth. Were they placed under conditions favourable to their development, their descendants would soon become full-sized horses, even in the case of ten-hand Shetland (Fig. 234) or Corean ponies. Selection, as in the case of toy-terriers, would of itself, if carried out strictly, enable us to maintain a breed of dwarf horses; but when with small size we also
require physical excellence, this application of selection would certainly prove too costly for practical requirements. Hence, in temperate climates like those of England and Australasia, horse-breeders are unable to maintain a race of ponies which are well fed and well cared for. Extraordinarily good polo ponies, like Dynamite (Fig. 237), and racing ponies, like Predominant, are more or less flukes in breeding. At the same time, we must not ignore the following three facts in this connection:—(1) That the respective offspring of certain sires and certain mares are abnormally small, (2) first foals are often smaller than subsequent ones; and (3) the produce of very old sires are frequently lacking in height.

**Thickness of Limb.**—Continuing the argument begun in Chapter I., we find that the muscles of the limbs of gallopers are comparatively long and slender. Hence, the bones, being dependent on the muscles for their shape, must partake of the same character. It is advantageous for another reason that they should be slight; for, were the bones of the legs of the galloper massive, the friction in the working of their joints would be proportionately increased, with consequent loss of speed, which would be of little importance in the heavy draught animal, in which the opposite kind of conformation should be sought for.

**Length of Neck.**—As the muscles which draw the fore leg forward (namely, those of the neck) are muscles of locomotion, they should be proportionate in length to those of the fore limb. Hence, if a horse has long fore legs, like the race-horse, he ought to have a long neck; and *vice versa*.

**Length of Head.**—As the head is a part of the spinal column (p. 24), its length, as a rule, will be proportionate to that of the spinal column; but will bear no fixed ratio to the length of the limbs, which varies according to the kind of work to which the particular horse is best suited. Thus, we find that although the length of the head has the same
Fig. 237.—Mr. J. E. Peat's English Polo Pony, Dynamite.

Fig. 238.—Mr. W. H. Walker's Montana Polo Pony, Montana Bill.
proportion (about $1 \text{ to } 2\frac{1}{2}$) to the length of the body in both
the racer and cart-horse, the comparison does not hold good
with regard to the height, which is naturally influenced by the
length of the fore legs.

**Width between the Fore Legs** shows strength of
the pectoral muscles (p. 31) which draw the fore limbs back,
and consequent weight on the fore hand. Hence the galloper
and jumper must be comparatively narrow in front; and the
cart-horse, broad.

![Fig. 239.—Fore Foot drawn up so as to touch the Elbow.](image)

**Comparative Weight of Body.**—The body of all
saddle horses should be as light as is compatible with the due
performance of their work; for any extra weight will be
carried at the expense of the soundness of their legs. It is
different with the harness horse, which has, comparatively, no
weight on his back. The heavy cart-horse requires a deep,
massive body for the attachment of his powerful muscles, and,
also, to give him the necessary weight to throw into the collar.
This subject has been discussed in Chapter IX. (p. 60).

**Comparative Length of the Bones of the Limbs.**—
If we "pick up" in succession the fore feet of a number of
differently shaped horses, and bend the limbs at the knees as far as they will "go," we shall find that in almost all cases, the heel will touch the elbow (Fig. 239) at about the same place. As the proportion between the length of the fore arm and cannon-bone evidentlly varies in different horses, a comparatively long or short fore arm must be accompanied by a similar condition of the bones below the fetlock. Lecoq remarks: "The length of the fore arm varies inversely as that of the cannon-bone." I think I may venture to extend this principle somewhat further, in stating the following inverse proportions:—Shoulder-blade, long; humerus (from point of shoulder to elbow joint), short; fore arm, long; cannon-bone, short; pastern, long. In other words, a long shoulder-blade is accompanied by a long fore arm and long pastern, and by a short humerus and a short cannon-bone. The converse of this holds equally good. Taking the shoulder-blade as the base to start from, we may infer that the difference between these alternate proportions should be best marked in animals, like the hunter or steeplechaser, which specially require to have this bone of considerable length (p. 184). It may be objected that the greyhound (Fig. 8), which is possessed of extraordinary speed and marvellous jumping power, has, comparatively speaking; a short shoulder-blade and long humerus. Although the length of the latter, which is detached from the body, gives him great forward "reach;" the shortness of the former makes him too bad a weight-carrier (p. 180) for him to be accepted as a model for our purpose. I think we may assume that a similar series of inverse proportions should exist in the hind limb. Thus: pelvis, long; thigh, short; tibia (from stifle to hock), long; cannon-bone, short; pastern, long. As the muscles which give length to the tibia are far more concerned in the extension of the hind limb of the jumper and galloper than in the cart-horse; we should look for greater length from stifle to hock, in the first two, than in the last-named. I would also expect in them a shorter thigh and a shorter cannon-bone. I may mention that I am confirmed in this
opinion by the practical experience of Mr. Tom Jennings, junr., the well-known trainer, who once remarked to me that he always regarded as a good point in a race-horse, the fact of its stifle being set high up in its flank—i.e., its having a short thigh bone, and consequently being long from its stifle to its hock.

In the remainder of the body we might, possibly, also find a series of inverse proportions as follows:—Head, short; neck, long; back and loins, short; croup, long; bones of the tail, short.

Although I am well aware that the proportions of the skeleton do not rigidly follow any strict mathematical rule; still I am strongly of opinion, from close study of the horse, that in the large majority of cases the foregoing deductions will be found to be correct.

**Differences of Conformation between the Two Sexes.**—As a rule, the mare, as compared to the horse, has a lighter neck, a broader pelvis, is higher behind and slacker in the loins, than he is.
CHAPTER XVI.

HEAD AND NECK.

Size of Head—Leanness of Head—Profile of Face—Front View of Face—
Size of Brain—Top of the Head—Ears—Eyes—Hollows above the Eyes—

Size of Head.—We have seen on page 136 that as the head is a portion of the spinal column, it should correspond in size to the bones of the back, loins, croup, and ribs, and not to those of the limbs. Agreeably to the axiom that "the function makes the organ," we find, in the majority of cases, that a horse's breathing capacity is proportionate to the size of his air passages, of which the cavities that lead from the nostrils towards the windpipe and lungs cannot be large, unless the bones which form them are of fair size. We must remember that a horse breathes, normally, through his nostrils and not through his mouth. Besides, as the tube (larynx) through which air enters the lungs from the nasal cavities, lies between the two branches of the lower jaw; it follows, speaking generally, that the broader and more open the nostrils are, the greater will be the calibre of this tube, and the more perfect the breathing power. Although it is impossible to draw any hard and fast rule on this subject, we may infer that a comparatively small head is not a desirable "point" in horses whose success depends on their power of breathing. I venture to think that men of experience will agree with me in saying that unusually neat and trim heads are far more common among "the five furlong division," than among genuine stayers. Again, the head should be of sufficient size to afford a broad surface for the attachment of the muscles of mastication, for those that extend, flex, rotate
and move the head from one side to the other, and for muscles which draw the limb forward, and which are, consequently, important agents of movement. The connection between the size of the head and the amount of intelligence possessed by an animal is, as with ourselves, too ill-defined to admit of any practical deductions being made from it. As the usefulness of a horse is generally limited by the amount of work his legs will stand, the possession of a large head by an animal which is "light of bone" in his extremities, is a serious defect; for it not alone shows that his frame is wanting in symmetry, but it also tends to indicate that the bones of his body, and, probably, the muscles and other tissues, are too heavy for his legs. If, however, he showed great substance and good quality of bone, tendon and ligament, we might very well "put up" with some "plainness" about his head. Any useless weight of that part, acting at the end of the lever formed by the neck, will naturally be objectionable. Agreeably to the facts mentioned on page 136, we may judge the length of the head by that of the body, the usual proportion being about 1 to 2½. Probably, a more practical rule is to compare the length of the head with the depth of the body at the lowest point of the back. In a well-shaped horse which is not in gross condition, these two measurements are very nearly equal; although the head, from its isolated position, looks much less long, at first glance, than the body is deep. Besides this, the fact of the body being round, while the side of the horse's head, as seen in profile, is flat, will cause the depth of the former to appear to measure more than the length of the latter. We may prove the approximate correctness of the ratio of 1 to 2½, by reference to the table given on p. 127. From it we see that in Ormonde the proportion is 1 to 2.5; in St. Simon, 1 to 2.48; in Cheadle Jumbo, 1 to 2.6, and in Chance 1 to 2.7. Here, possibly to our surprise, we perceive that the cart-horses have comparatively smaller heads than the racers—a difference which, no doubt, is due to their grosser "condition"; as the fat on their chests and quarters must add slightly to their length of body.
Bourgelat, followed by all, or nearly all, the French writers on equine conformation, adopted the length of a horse’s head as a measure of its height, in the proportion of $1$ to $2\frac{1}{2}$. This eminent Frenchman based his calculations on a type of horse (such as the ordinary saddle nag) which was about as high at the withers as it was long in the body, and did not take into consideration the great differences between the respective heights and lengths of animals of various classes, ranging from the racer to the Shire horse. From my own observations, I would put the length of a horse at from $2\frac{1}{2}$ to $2\frac{3}{4}$ times the length of his head.

The fact that the size of the head of the horse is proportionate to his length of body, and not to his height at the withers, accounts for the cart-horse appearing to have a comparatively larger head than the thoroughbred.

**Leanness of Head.**—In the lighter classes of horses, the head should present a general appearance of “leanness,” that is to say, the skin which covers it should be fine; its bony prominences sharply marked; and the muscles, blood-vessels, and nerves which are immediately under the skin, clearly defined.

The absence, thus indicated, of an excess of loose underlying tissue will suggest the possession of strength of muscle and bone (p. 12). When the head is large and “fleshy,” we may generally assume that the animal is “soft” and wanting in “blood.” The presence on the head of well-developed muscles, of which those of mastication are the most powerful, will naturally suggest to the observer that the horse has a good constitution. As pointed out by Goubaux and Barrier, we must not mistake for “leanness” an emaciated or wasted appearance of the muscles, due to old age or debility.

The Bombay Arab dealers (such as that fine judge, Ali bin Abdullah, and that prince of Bedouins, the late Shaikh Esa bin Curtas) regard thinness of the lower jaw at its angles as a sure sign of pure desert blood.
Profile of Face.—The line of the forehead and nose, when viewed in profile, will, as a rule, be straight, concave or convex. The first two forms of contour are more or less characteristic of the thoroughbred and Arab (Figs. 323 and 244); although it is only correct to say that many horses of aristocratic English blood have Roman noses, especially those bred in the Colonies. I have never seen a high caste Arab have such a conformation. The true concave face is obtained, not by a prominent forehead, as in Fig. 245; but by a dip in the nose between the eyes and nostrils (Fig. 244). Ormonde’s face (Frontispiece) tends to concavity. For a convex profile (Roman nose), see Fig. 246. This shape might be objected to on account of its liability to render the air passages of the head curved, instead of straight, in which case there might be some light interference with the ready ingress and egress of respired air. I have, however, never met with a case in which a Roman nose was the cause of impaired breathing power; although I have known a horse become a roarer from alteration in the shape of the nasal cavities from a disease of the bones called osteoporosis, or “big head.” I may mention that many heavy cart-horses have Roman noses.

Colonel John Anderson, late Inspecting Veterinary Surgeon, Bombay Army (than whom no better judge of a horse exists), remarked to me many years ago, that a prominent forehead (Fig. 245), or a rise between the eyes, is an indication of a bad, or at least of a wayward, temper in a horse. I have no theory to advance in support of this idea, the truth of which, however, I have seen verified in many instances. The original of Fig. 245 was a rascal of the deepest dye. Tristan (Fig. 240) had this fatal bump between his eyes, and he was a “thief,” as well as a bit of a “savage.” His name will recall to many old race-goers the memorable struggle for the Cambridgeshire of 1881, when, ridden by poor George Fordham, he finished third to Foxhall and Lucy Glitters. It is but just to the chestnut son of Hermit and Thrift to say that his trainer, Mr. Tom Jennings, junr., tells
me that Tristan's temper had been spoiled by bad usage when he was a yearling.

**Front View of Face.**—Good width of forehead between the eyes (Fig 248) indicates, as a rule, free breathing power and strong muscles of mastication, for the bones of that part (frontal bones) form a portion of the roof of the cavities through which air enters on its way to the lungs, and gives attachment to a powerful muscle which aids in closing the jaws, and which is fixed in the large depression that is just above the eye. Good width between the eyes is generally regarded as a sign of intelligence and of a generous disposition; and it may indicate large capacity of brain, by reason of the frontal bone forming a portion of the covering of that organ. I shall refer, under the next heading, to the subject of the desirability, or otherwise, of a large brain in the horse.
M. H. H.

Fig. 241.—Head of High Caste Arab.

Fig. 242.—Head of High Caste Arab. To face p. 144.
FRONT VIEW OF FACE.

As seen from the front, the bones at each side of the head, from the outside corner of the eyes to the hollow above the eyes, should run nearly parallel to the long axis of the head, and should then narrow inwards. This desirable shape is well shown in Fig. 251. If the reader will compare this photograph with Fig. 252 he will see my meaning; for in the latter, the line from the outside corner of the eye to the base of the ear is nearly straight. This peculiarity and a certain fulness of nose (which is very different to the fine modelling of the nose in Fig. 251) gives a coffin shape (Fig. 243) to the head in Fig. 252. I may mention that this head is slightly foreshortened, and consequently does not appear as narrow as it ought to be. I need hardly say that I am aware that the stable term, "coffin-shaped," as applied to a horse's head, has reference to its appearance in profile, and not to its front view.

Experience tells us that the forehead should be prominent immediately below the brow-band, and should be marked on each side by a well-developed lump of muscle which is shown fairly well in Fig. 251. This formation, I am inclined to think, is usually accompanied by the possession of pluck and "cleverness"; but can give no reason for this opinion. Its good or poor development is, I regret to say, as difficult to
clearly explain in words as it is to show in a photograph; although its recognition in actual practice is an easy matter.

It is regarded as a beauty for the eyes to be set high up in the head. As far as I can see, their position varies but little in the horse. In the mountain zebra (Fig. 257) they are set rather low down.

The bones on the sides of the nose are prominent in youth, but gradually "fall in" with age, on account of the fangs of the back teeth, which are lodged in them, descending lower and lower as the animal grows older.

This change in the form of the nose will serve to indicate, to some extent, the age of the horse.

**Size of Brain.**—Without entering into any physiological argument we may assume that, as a rule, size of brain is an indication of brain power. According to the classic idea entertained by writers on equine conformation, a large development of brain is a desirable "point" in the horse. Thus we read in *Achat du Cheval*, by Gayot, that: "The more voluminous is the brain, the larger is the spinal cord, proportionate to the size of which are the nerves that issue from it. It is thus that a large forehead, denoting a high degree of intelligence, is the index of a good nervous system—that is to say, of high mental and physical qualities." As regards this, I would suggest a doubt respecting the connection claimed between "high mental and physical qualities." It did not exist among the ancient gladiators, nor does it in the case of our modern prize-fighters and pedestrians. Although the bull-dog is stronger and the greyhound faster for their size than the poodle and collie, they are certainly not more intelligent. A long and intimate acquaintance with horses—especially that acquired during my professional horse-breaking tours—convinces me that a comparatively high degree of mental (i.e. reasoning) power is not desirable in a horse; because it is apt to make him impatient of control by man. A jibber in harness, or a refuser in the hunting-field, when the vice has not been induced by pain or infirmity, such
M. H. H.

To face p. 146.
as galled shoulders or weak hocks, usually "baulks" because "he knows too much," or at least he knows more than the animal that will pull at the traces or follow the hounds till he drops. So far from a horse taking delight, as he is supposed by novelists to do, in obeying the wishes of man, he very seldom yields to his would-be master without a struggle. If this takes place in the hoped-for manner, when the horse is quite young, the victory on the part of the man is generally easy, and a few repetitions of it quickly confirm the habit of obedience. If, however, the attempted subjugation be delayed till the animal is "aged"—when he will be able to think for himself without the promptings and influence of man—it will be found that his breaking will be ten, if not a hundred, times more difficult than if it had been undertaken in his early youth. This theory of the undesirability of a horse knowing too much, which I have applied to refractory animals, appears to hold equally good in greyhounds that run "cunning." In these remarks on the intelligence of horses, it must be clearly understood that I refer to reasoning power and not to power of memory, which is independent of the capacity to draw conclusions from given premisses. It is evident, without the necessity of writing a treatise on the subject, that the useful (to man) intelligence of the horse lies in his power of memory and in the quickness with which his muscles act in response to the impressions received by his senses. In other words, his useful intelligence depends on the high development of his instinct, and not of his reason. We demand of the horse ready obedience; but not obedience matured by reflection, like what the shepherd would expect his dog to display when getting his flock home on a stormy night, or when driving them through a crowded thoroughfare. We do not ask him to take the initiative from the deep affection which he does not bestow on us, nor to reason out problems; we only want him to remember that if he does certain things, we shall "make much of him"; that if he does other things, we shall punish him.

We know that reflex action, prompted by stimuli from
outside the body, acts best when it has but little connection with the brain. In fact, the smaller is the comparative size of the brain, the quicker and more accurately are instinctive movements performed. Thus we see animals with, comparatively, a very small brain, or with none at all, get out of danger, or seize their prey, with an amount of speed and precision which it would be hopeless for any man to attempt to rival; simply because the action of his instinct is impeded by the influence of a large brain. We find this demonstrated in ourselves, in the case of movements which, like those in fencing, boxing and dancing, for instance, could be executed only slowly and clumsily at first, when they needed the exercise of thought, become capable of being performed with the speed and correctness of a machine, as soon as practice had made them almost automatic.

The prominent forehead (Figs. 245 and 250), to which I have alluded on p. 143, indicates a large size of the intellectual portion (cerebrum, p. 35) of the brain, which at that part of the forehead is covered by only a thin plate of bone. Without wishing to import any of the jargon of phrenology into a discussion on this subject, I may hazard the suggestion that the portion of the brain which is consecrated to the functions of memory and perceptive power, as well as the cerebellum (the organ of "muscular sense," p. 35), lies underneath the upper part of the forehead, where prominence and convexity of the part is a marked beauty, as I have mentioned on p. 145.

For the foregoing reasons, I do not look upon the possession of a large brain as a desirable "point" in a horse. Hence, apart from the practical experience I have had, I do not like, as I have just said, a bulging-out condition of the lower part of the forehead, nor a long distance between the eyes and the top of the head (p. 146), both of which peculiarities of conformation point to large brain capacity.

Top of the Head.—The bone (the occipital crest) at the top of the head should be prominent and well developed,
Fig. 245.—Prominent Forehead.

Fig. 246.—Roman Nose.

Fig. 247.—Roman Nose, Ewe Neck, and Upright Shoulders.
as it affords attachment for the powerful suspensory ligament of the head and neck (p. 28), and for several important muscles. Large development of the occipital crest (Fig. 254) is considered by some authorities to indicate corresponding size of the cerebellum.

**Ears.**—Personally, I cannot say much as regards the indications afforded by the ears. In common, probably, with most observers, I have remarked that animals which move their ears in a quick decisive manner, evidently with the same intent as they use their eyes to see what kind of ground they are going over, are, generally, of the "clever" sort which do not know how "to put a foot wrong." Their method of employing their ears is quite different to the restless, "listening" (if I may use the word) style adopted by horses that have defective sight. The former have their attention chiefly directed to the ground in front of them; the latter distribute it on all sides. It looks well for the skin and hair which covers the ears to be fine, and the ears themselves thin and lean. Whether in horse or man, I dislike to see ears set up high on the head, and think that the part of the skull which is between them should be moderately broad, as in Fig. 248. At the same time, I must say that I have seen many clever horses, especially among those bred in India, that had their ears close together and set up high on the head, as in Fig. 253. This photograph gives us an idea of the peculiar manner in which the points of the ears of some Indian breeds (Kathiawars and Wuzeerees, for instance) are directed inwards when the ears are pricked forward. To show what diverse opinions exist as to the ears of the horse, I give from different works on conformation the two following extracts, which are far from being in accord with each other. The reader, however, can decide from his own practical experience as to their respective correctness. "There can be no greater ornament than long, fine, active-looking, upright, tolerably close-set ears, with the points a little inclined towards each other. I never saw
a soft constitutioned horse with ears of this description" (Carson). Goubaux and Barrier state: "It is a fact worthy of notice that horses which have short ears are always energetic and plucky. There seems to be a certain relation between their length and the timidity of their bearers. At least, this is the conclusion we may draw from a comparison made among different kinds of animals, of which the most timid and inoffensive have them greatly developed. Carnivorous animals, on the contrary, have them small. Short ears render the head lighter, and the expression of the face brighter, more expressive and more pleasing to the eye. In this respect the Arab horse greatly excels English and continental animals. It is considered a beauty for a horse to have his ears well directed to the front at an angle of about 45° with the axis of the head. Quick and energetic animals carry their ears in this manner. To sum up, the ear is beautiful when it is short, directed to the front, well placed, lean, fine, and covered with thin skin, which should be adherent, and comparatively free from hair in the interior of the ear." With respect to the ears being "well directed to the front at an angle of about 45° with the axis of the head," I may remark that such a carriage of the ears, being produced by voluntary muscular effort, can be sustained only for a comparatively brief space of time. Almost all horses which are not prevented therefrom by disease, malformation or accident, have the ability to direct their ears forward in the manner mentioned; but do so only when their attention is attracted to something in front of them. The same may be said of donkeys, mules and zebras (Figs. 257 and 258). It is true that some horses "prick their ears" more frequently than others; but, for all that, such carriage of the ears can be regarded as but a temporary lighting-up of the face, and not as a permanent beauty. I may add that if a horse habitually carries his ears more or less directed behind him, we might suspect him to be wanting in courage and good temper. This is by no means an invariable rule, for I have met some notable exceptions.
Fig. 248—Broad Forehead.

Fig. 249—Stripe and Snip.

Fig. 250—Prominent Forehead.
Richard remarks that deaf horses carry their ears steadily pointed in the direction the horse is looking, without side "play." Such animals are generally docile and attentive to the indications received from the rein and leg.

A horse is said to have lop-ears (Fig. 256) when they are usually carried in a loose and somewhat pendulous manner, and they therefore lack the frequent forward, backward and lateral play of those of the ordinary horse. Although increased size naturally directs attention to this peculiarity; lop ears are not necessarily large ears. A lop-eared horse is quite as capable of pricking his ears forward as any other horse; but having done so, he generally allows them to fall back into their accustomed pendulous position. Lop-eared horses are generally supposed to be more placid in disposition, if not more sluggish, than their fellows.

**Eyes.**—The eye should be clear and free from tears, the pupil black, and the eyelids thin and comparatively free from wrinkles. A small eye (Fig. 247) in the horse is called a "pig-eye," and is generally considered to denote a disposition that is either sulky or wanting in courage. In this photograph, the straight shoulder, ewe neck, Roman nose and pig-eye point to the plebeian origin of the animal whose portrait it is. The prominent "buck-eye" is generally regarded as an unfailling sign of short sight, which is, however, a very rare defect in horses. Horses which show a good deal of white in their eyes, as the term is, are usually suspected of being vicious; for kickers, as a rule, uncover a portion of the white of the eye (on the side to which the head is turned) when they look back ready to "let fly." This suspicion is naturally heightened if, at the same time that the danger signal in the eye is displayed, the ears are pressed back close on the neck, the front teeth are exposed by the drawing back of the lips, and a hind foot is kept raised off the ground. I have, however, known horses of most placid temper whose eyes showed a great deal of white all round the *iris* (the coloured portion
of the eye), on account of the iris being abnormally small.

I may mention that, under ordinary conditions, the human eye always shows a good deal of white, but that the horse's eye, as a rule, does not do so, except when its glance is directed to the rear or inwards. Some game, honest horses (like St. Gatien, for instance) show, without looking in a backward direction, a certain amount of white of the eye, which, when it is of a constant reddish tinge, is thought by some to mark hardiness of constitution and staying power.

**Hollows above the Eyes.**—The existence of deep hollows above the eyes is objectionable, for it denotes that the animal is old and more or less worn out, or that either its sire or dam was well advanced in years when it was bred, and, consequently, that it is somewhat wanting in vigour.

**Nostrils.**—The nostrils should be thin, flexible and of large capacity, so as to suggest the possession of large air passages. During rest they should be more or less closed. If they are kept constantly dilated when the breathing ought to be tranquil, we may infer that the animal has something wrong with his "wind."

**Lips.**—The lips should be lean and comparatively thin; should possess considerable power of movement; and, as a rule, should be kept closed, for the sake of appearance. We may generally consider that a pendant condition of the lower lip indicates want of vigour; for it is much more frequently observed among old horses than among young ones. Richard considers that it is often inherited. "We have," says he, "ridden horses full of energy, which had a pendant lower lip. Delphine, formerly a brood mare at the stud at Pin, daughter of Massoud and of a Selim mare, dam of Eylau, had a drooping lower lip, and all her foals took after her in this respect. She, however, possessed energy and blood which have left their mark." Some horses have great
**Fig. 251.**—Head of Well-bred Horse.

**Fig. 252.**—Head of Underbred Horse.

**Fig. 253.**—Turned-in Ears.

**Fig. 254.**—High Occipital Crest.
length of upper lip, which undoubtedly looks ugly. Both this conformation and the possession of a thick tuft of hair or moustache on the upper lip, are indicative of coarse blood.

**Lower Jaw.**—The branches of the lower jaw should be broad, as viewed from the side, and should be wide apart at their angles, so as to give plenty of room for the tube (the larynx) which lies between them, and which opens into the wind-pipe. The space between the jaws should not alone be broad, but should also be hollowed out, a condition which will show that the parts are of firm texture and free from excess of loose connective tissue (p. 12). The old practical rule of finding whether a horse is wide enough between the jaws, is to try if the clenched fist can be placed within the hollow. I venture to think that few horses could successfully pass this test, if it were applied with an ordinary sized man’s hand. When this space is broad and well hollowed out, the horse will naturally be able to bend his head more freely than when it is narrow, and he will, consequently, be pleasanter to ride and drive.

**Setting-on of the Head.**—The part where the head is set on to the neck should be lean and muscular, and should show a slight depression behind the ears and lower jaw, and also above the wind-pipe. This will indicate absence of an excess of loose connective tissue and ability on the part of the horse to bend his head freely. The beautiful manner in which the neck “runs into” the head of some horses, is due to the arrangement of the bones of the neck and to the lean and well-developed condition of the muscles. The profile of this junction will, then, form a curve which will be a fitting commencement of the graceful, undulating line that sweeps over the neck, slightly dips in front of the withers, over which it curves, and rising a little along the back, swells boldly over the loins and quarters, dips again at the root of the dock, and, finally, ends in the flowing lines of the tail. The setting-on of the head and the curves alluded to were
beautifully exemplified in St. Simon, whose photograph (Fig. 9) is not nearly as good as I could have wished. These points also come out well in Florizel II. (Fig. 323), Favonius (Fig. 324), Predominant (Fig. 236), Blitz (Fig. 370), and Romance (Fig. 270). In the Arab pony, The Brat (Fig. 371), the curved line is perfect from the head to the croup, but, on account of the way he is standing, it descends too abruptly from the top of the croup to the tail. In Ormonde (Frontispiece) the head is set on to the neck in a coarse, stiff manner. The ideal contour which I have described, is evidently an affair of beauty rather than of usefulness.

Neck.—As the length of the neck indicates the length of the muscles which draw the shoulder forward (p. 31), the more we seek for speed and ability to jump cleverly in an animal, the longer should be his neck; its thickness being limited by the amount of strength the muscles have to put forth. The race-horse, hunter, and fast trotter, therefore, should have a long and comparatively thin neck, and the other classes should have their necks proportionately shorter and thicker according as they recede from the racing and 'cross country type and approach that of the heavy draught animal. The operation of this rule should be restricted only so far as to allow sufficient length of neck for grazing purposes. Some heavy cart-horses have such short necks that they cannot feed off level ground with comfort to themselves. When the art of breeding is pushed to such an extreme as this, I cannot help thinking that there must be some defect in its practical working. It is evident that the combination of a large head and a thin neck is not alone unpleasing to the eye, but is almost always a sign of general weakness.

The all-essential power which men possess to guide and regulate the movements of a horse, largely depends on the flexibility of the animal's neck. Were we unable to make him bend it, and to oblige him to turn his head to one side or the other in obedience to the "feeling" of the hands on
Fig. 255.—Mr. W. H. Walker’s Specs.

Fig. 256.—Lop-eared Thoroughbred Mare.
the reins, he would be all but useless to us in saddle and for ordinary harness work. With reference to this subject, I may mention that I once undertook to saddle and get ridden an old entire zebra (*equus zebra*, Fig. 257), whose feet were becoming gradually deformed, on account of its not permitting them to be pared down from time to time. In less than an hour after I had turned it into the ring of Frank Fillis's circus, which was then in Calcutta, I had its feet rasped down to a proper level, and had it saddled and bridled for the first time in its life. It was then ridden by Steve Margarett (a brilliant Australian rough-rider) and by my wife. This was certainly the first occasion a lady ever rode this variety of zebra, which has the reputation all over the world of being unrideable. Although I was able to quickly teach it to carry its unwonted burden quietly, I made far less progress in giving it a "mouth," during the two days I had it in hand, than I would have done in half an hour with any wild Colonial horse caught for the first time on a "run;" the reason being that the zebra's neck was so stiff and strong, that I was unable to bend it in any direction. I soon taught it to do what I wanted in the circus, but when I rode it outside, it took me wherever it liked. In fact, I had not the slightest power to either stop or guide it. Some horses, like this striped ass, though not to the same extent, are very stiff in the neck, a fact which may be owing to an obstinate temper, bad breaking in, or to a thick and rigid condition of the muscles and joints of the part. This natural want of flexibility may be overcome to a great extent by judicious "bending." As it militates against the ready turning and easy regulation of the paces of an animal, it should be regarded as a grave defect of conformation in the saddle-horse and light trapper. It may, however, be overlooked in the heavy cart-horse, whose normal pace being a walk, will not require to be as "supple" (to use a riding school term) as an animal that has to go at a faster pace, and whose line of progression, instead of being along a more or less straight road, may be across an intricate country, or in conformance
with the word of command in a riding school or on parade.
Besides this, to have the necessary power in his fore limbs,
the heavy draught animal will need massive neck muscles
(p. 31) to draw them forward. When "cleverness" is
essential to a horse, he should have a flexible neck, and
should be able to bend and extend it with the utmost facility,
so as to use his head and neck as a balancing pole for
preserving the equilibrium of his body.

Some extra weight in the neck, apart from that required
for the due development of the neck muscles, will probably
be no detriment to the usefulness of a powerful cart-horse;
for it will aid him in "throwing weight into the collar." In
the saddle-horse, on the contrary, it would be a great dis-
advantage, because it would make him heavy on his fore
hand, and would consequently render him liable to pre-
maturely wear out his fore legs. In this connection, I may
point out that entires, who, as a rule, have much heavier
necks than geldings, do not, when they are employed at
fast paces, stand as much work, retain their "form" as
long, or get into galloping condition as quickly as those
which have been "added to the list." We see this rule
well proved in steeplechasing and racing, as witness the
long careers of those geldings, Liberator, Regal, Gamecock
(Fig. 259), Reindeer, and others. For races in the early
part of the season in England, geldings as a rule can be
got much fitter than entires; as they require less work. As
maturity of horseflesh is required far more at steeplechasing
than at flat racing; the superiority of the gelding over the
entire is particularly observable "between the flags." Owners and trainers who recognise the advantage of
castrating those colts of theirs which do not give promise
of value for stud purposes, are often deterred from putting
the operation into practice on account of geldings being
ineligible for many flat events. This prohibition extends
on the Continent to a few steeplechases. I think I may
safely say that the large majority of colts which are not
worth keeping entire for future stud purposes, should
Fig. 257.—Mountain Zebra.

Fig. 258.—Burchell's Zebra.
be cut not later than the end of their two-year-old racing career. The records of hunting amply prove the benefits of the operation. Mr. H. T. Barclay's Freeman, who carried his master most brilliantly for fourteen trying seasons over Leicestershire, is no solitary instance of the ability of the gelding to stand work, especially when it is of a nature, like that of jumping, to severely tax the soundness of the fore legs. The necessity of the hunter to be light in front, is a subject upon which I need not dwell here. Many experienced trainers with whom I have discussed this subject, hold the same opinions as I do on the practical utility of castration. I think that the majority of trainers will agree with me in saying that geldings not alone stand fast work better than entires; but also recover more quickly from injuries of the fore legs. The lesson to be learned, from a conformation point of view, from the foregoing remarks, is that the racer, chaser, and hunter should be light in the head, neck and shoulders.

As regards the contour of the neck, I may state that, according to its shape, it is designated high-crested (or convex, Fig. 334), straight (Figs. 322 and 329), or ewe-necked (concave, Fig. 247). The contour varies a good deal according to the manner the animal holds his head, and should be judged by the form it assumes when the horse stands in an ordinary manner at attention (p. 62), with the line of its face at an angle of about $45^\circ$ to the ground. Some horses, especially coarse bred entires, have a very high and thick crest, from an excessive amount of fat having been deposited above the suspensory ligament of the head and neck. Such a formation, from overloading the fore hand, is a marked defect in any kind of saddle-horse. A slight convexity of crest in a lean though fairly muscular neck, as in Fig. 371, is a beauty.

The fact of a horse being ewe-necked seems to be of no detriment to his speed. It might, however, affect his handiness, on account of depriving, to some extent, his rider or driver, as the case may be, of command over him, and
by causing his head to be brought into a direction which might prevent him seeing clearly where he was going. On page 67, et seq., I have discussed at some length the subject of the carriage of a horse's head and neck.

In saddle-horses, the place where the neck comes out of the chest should be marked, above, by a slight depression in front of the withers, below, by another depression at the point where the jugular groove meets the chest, and at each side, it should be nearly flat with neck and shoulder. In cart-horses, the large muscles of the shoulder stand out in prominent relief from the neck, and the dip in front of the withers is either absent or but faintly indicated. Owing to the comparative lightness of the neck in mares and geldings, the union of the neck with the head and trunk is better marked in them, than in entires.

Throat.—The wind-pipe should be large and well detached from the neck; as it will then indicate good breathing power. I have noticed that roaring often accompanies a wasted appearance of the tissues which cover the larynx. I am of course aware that the typical form of roaring is caused by paralysis of one or both of the muscles which open the larynx; and that their size is too small to account for the peculiarly emaciated condition to which I have alluded.

CHAPTER XVII.

THE TRUNK.

General View of the Trunk.—We have seen on p. 133, that, as the work which the organs (heart, lungs, liver, spleen, stomach, intestines, kidneys, etc.) contained in the trunk have to do, is the same, whatever may be the kind of horse; the shape of the trunk will not be affected by class distinctions. In this particular, the conformation which will, for instance, be most suitable for a Derby winner, will be that which is best for a cart-horse. In laying down this general rule, I must make an exception of the withers (p. 166), which are concerned in locomotion, and not in the performance of any vital function. Although the shape of the horse's body remains constant—without, of course, taking into consideration individual peculiarities—the bones which make up the entire structure should agree as to thickness with those of the legs; for several of the muscles that are attached to them, are also attached to the limbs. It has already been remarked that the strength of a muscle more or less regulates the thickness of the bone to which it is fixed.

In all cases, the body should be as short as possible compared to its depth; or, in other words, as deep as possible, compared to its length. The longer it is, the further removed will the fore and hind limbs be from each other, and the less able will the animal be to carry weight. On p. 53 we have seen that a short body is a desirable point in the race-horse and jumper. In draught, also, any undue length of body is a disadvantage; for the farther the fore and hind
legs are apart, the less rigid will be the connection between them, and the less efficiently will they work together. When speaking of the depth of a horse’s body, I refer to its depth at the lowest point of its back (Fig. 11). If an animal shows a good measurement at this part, he is almost certain to possess fair substance of body. The measurement from withers to brisket is very fallacious; for it is not alone affected by the height of the withers themselves, but it also affords hardly any indication of the nature of the “centre-piece” of the body. Many horses which are very light in their loins and back ribs have good depth from withers to brisket, as in Fig. 268. In different horses, the length of the body varies from about 2.4 to 2.8 times its depth.

**Chest and Ribs.**—Although the heart, as well as the lungs, is contained in the chest, I shall not consider it here, for I can offer no clue as to its action from the consideration of the conformation of the chest, which is influenced chiefly by the shape, size and setting-on of the ribs. The points which we should seek for in the ribs of the horse, in order to obtain the best possible breathing power, are —

1. Convexity or roundness of ribs (“barrel”) behind the shoulders.
2. Good length of ribs.
3. Ribs well inclined to the rear.

I may explain that the convexity of a curve may be measured by the proportion which its height \((c\, d, \text{Fig. } 261\text{ or Fig. } 262)\) bears to the length of its chord \(a\, b\). Thus, if \(c\, d\)

\[
\frac{c\, d}{a\, b}
\]

is equal to \(\frac{1}{3} a\, b\) in Fig. 261, and equal to \(\frac{1}{6} a\, b\) in Fig. 262, the curve \(a\, c\, b\) will be three times as convex in the former as in the latter.
Fig. 263.—Gulf Arab.

Fig. 264.—Cahili Horse.
Among the higher animals we find that chest capacity is obtained either by convexity or by length. Hence those species which have short chests have round ones, and those that have long ones have them flat-sided, the capacity being increased by roundness of the ribs and decreased by flatness of these bones. We have already seen that undue length of body is detrimental to speed, weight-carrying power, and strength in draught. Consequently, we should seek for roundness of chest in order to obtain good breathing power.

Youatt, in his book on The Horse, appears to have originated a fallacy concerning the conformation of the ribs which has been repeated by many English writers. He says that “the circular chest could not expand, but every change of form would be a diminution of capacity.” This statement seems to be based on the supposition that the chest expands and contracts by the ribs opening and closing in a direction at right angles to the length of the body. Instead of this being the case, the difference in capacity of the chest is due to the fact of the ribs, which are inclined to the rear, turning round
towards the front on their upper and lower ends, as on pivots, when air is drawn into the lungs, and then revolving back again when the air is expelled from them. I may explain that the (tidal) air is expelled from the lungs by the elastic recoil of the ribs, which takes place the moment the muscles which drew the ribs forward become relaxed. Youatt's statement is altogether incorrect; for the rounder the ribs are, other things being equal, the greater will be the difference of chest capacity when the lungs are full to what it would be when they are comparatively empty.

We may prove the foregoing remarks as follows: Let the shaded oval in Figs. 265, 266 and 267 diagrammatically represent the space respectively enclosed between three pairs of ribs of different degrees of convexity, but of the same depth, viewed from behind, at the end of an expiration. Let $a b$ ($= a b'$) be, respectively, the distance of the centre of each rib from its vertical axis, $b a c$ the angle at which the ribs in all three figures are inclined to the rear, and $b' a b$ the angle through which they respectively turn during an inspiration. We shall then see that the difference of capacity—shown by the difference of area between the shaded oval and the one which circumscribes it—is greatly in favour of the round barrel. If it were possible to have a chest perfectly circular (as in Fig. 267) at the end of an expiration, the transverse axis of the chest, when the lungs were fully inflated, would exceed in length the vertical axis.

The second desirable condition—namely, good length of ribs—should, as we have seen, be obtained rather by rotundity than by the distance which the ends of the ribs respectively are from each other. Given ribs sufficiently round, we need not trouble ourselves much as to their length, except as regards the farthest back ones, which should be as long and directed as much outwards as possible, so as to afford a broad attachment to the diaphragm (p. 38). It would be easy to prove that the more inclined the ribs are to the rear, the greater will be the difference in capacity of the chest when empty to what it would be when full of air, and, consequently, the better the breathing power; but I do not think that it is possible to estimate this inclination with sufficient accuracy to make it a practical guide. My experience leads me to conclude that all useful purposes in this respect will be
Fig. 268.—Thoroughbred, "Weed."

Fig. 269.—Captain Woolmer's Minden.
served by satisfying ourselves whether or not the horse under examination is "well-ribbed up." If the last rib be short, flat, and but little inclined to the rear, the animal will be "slack in the loins," and most certainly will not have as good breathing power as he would have had if that rib had been long, "springing" well out from the side, and inclined so much to the rear, that there would be space only for the ends of two or three fingers between it and the point of the hip. Such a desirable shape would give the utmost width of base to the diaphragm, which is a very important muscle of breathing. Although I mention in this connection only the last rib, I take for granted that its neighbouring ribs would conform, more or less, to its length, shape and inclination to the rear. From the foregoing considerations, I would regard roundness of barrel behind the girths; depth of body (as compared to length of body) in the centre of the back; and being well ribbed up, as the great signs in conformation, of a horse having good breathing power. As "the middle false ribs are those which have the greatest power of being drawn forwards and outwards" (p. 29), they, in comparison to the length of the body, should be as long, as well as convex, as possible. On account of their lower ends being difficult to trace in the living animal, we may conveniently judge of their approximate lengths, by the depth of the body at the centre of the back, making due allowance for the "condition" of the animal. If we examine the Frontispiece and Fig. 268, which show three horses in training for racing, we shall notice that the back ribs of both Ormonde and Cloister were of good length, thus indicating fine breathing power; and that those of the "weed" were unusually short. As might have been expected, this mare, though fast, was a very poor stayer. I need hardly say that the shape of the body should be judged by the body itself, and without reference to the length or substance of the legs. The fact, as often occurs, of the body being too heavy for the legs, in no way affects the proportion which its length, depth and thickness bear to each other. The popular term,
"slack in the loins," which I have used, is applied to the objectionable condition of the last rib being short and at a considerable distance from the point of the hip. As this kind of conformation usually accompanies a more or less weak state of the muscles of the loins, the expression is not altogether inappropriate. Some persons ignorantly think that it is an advantage for a horse, as regards speed, to be a bit "slack in the loins;" because (so they say) such a shape allows the animal more freedom in bringing his hind legs forward, than if he were well ribbed up. I need hardly point out that the form of a horse's back ribs cannot in any way affect the action of his hind legs. This absurd notion was, no doubt, started by some person who supposed that the hip joints were at the points of the hips! Owing to sexual causes, mares, as a rule, are not so well ribbed up as horses. Hence some slight slackness in the hollow of the flank is not such a grave fault in them as in entires and geldings. The fact, however, remains, that for all purposes of work, a horse or mare cannot be too well ribbed up.

Merche remarks that: "Among common horses, the last rib is less arched and less carried back than among blood horses; and the flank consequently appears longer."

St. Simon, among many other great race-horses, was an instance of a fine stayer, who possessed singularly little depth at the withers, but had great roundness of chest behind the girth, and also fair depth of body at the lowest point of his back. It is essential for the race-horse to obtain good breathing power by roundness of ribs, so that his body may have its powers of breathing fully developed without its length being unduly increased.

The great advantage of depth in the front portion of the chest is to allow of good length of shoulder blade, which is indispensable to the weight-carrier and jumper.

Abdomen.—We have seen on p. 37 that the trunk is divided by the diaphragm into two portions, the chest and abdomen; the former containing the lungs and heart; the
Fig. 270. — Mr. Vansittart's Australian Horse Romance.

Fig. 271. — Underbred Australian Horse.
ABDOMEN.

latter, the stomach, liver, intestines, bladder and other organs. The ribs form the walls of the chest. The contents of the belly (consisting mostly of the intestines) are kept in their place chiefly by powerful ligaments, the principal one of which is the abdominal tunic (p. 28), and by muscles. These structures are respectively attached to the margin of the front part of the pelvis, to the rear part of the breast bone, rearmost edge of the ribs, and to the sides of the loin vertebrae, thus bridging over the vacant space. We may, then, fairly assume that the lines of the abdomen should form a continuation of the general contour of the chest. As the straight muscle of the abdomen which covers the lower portion of this cavity, is the chief muscle that bends the back, the horse cannot be thoroughly "fit" for work, if this muscle is unduly pressed down by the intestines, and is consequently prevented from contracting to its full extent. This straight muscle and the other muscles of the abdomen aid in the process of breathing, which will be more or less interfered with, if these muscles have to constantly strive against undue pressure from the contents of the cavity they cover. Besides, if the intestinal mass is greater than it ought to be, it will hamper the action of the lungs by forcing the diaphragm too far into the chest; it will add to the weight to be carried; and will militate against speed by tending to bring the centre of gravity to the rear, and by thus increasing the stability of the equilibrium (p. 41). Although the subject of feeding is not within the province of this book, it may not be out of place if I mention that the practice of giving horses large quantities of soft food (boiled turnips, for instance), which they can quickly consume, exerts, among other evils, a very injurious effect on the muscles of the stomach, intestines and abdomen; for, being deprived of the rest which is necessary to their repair and development, by the continued pressure resulting from the presence of the bulky food, these muscles soon become ill-fitted to perform their work. On the other hand, we should guard against a "tucked up" condition of belly, which will indicate illness,
over-work, too excitable a temperament, or improper management of some kind. If we consider that these abdominal muscles act by tending to become straight between their points of attachment, and that when in a passive state they are longer than when they contract, we shall see that, when in a condition of rest, they should be gently rounded, and should be neither drawn straight nor bulged out. In Chapter XXII., I shall consider the special development of these muscles.

Withers.—The chief object which the withers fulfil, is to afford attachment for the suspensory ligament of the head and neck; for muscles which extend the head and neck; for muscles that draw the shoulder blade forward; for the powerful muscle that runs along the top of the back and extends the vertebrae; and for a muscle which aids inspiration by bringing the ribs forward. If we look at the skeleton (Fig. 12), we shall readily see that the fact of the withers rising, as they do, above the line of the back, greatly assists the action of the elastic ligament that supports the head and neck, and of the muscles which extend these parts. It also increases the power of the muscle which extends the back and loins. Besides, it tends to give length to the muscle which is attached to the withers and which helps to draw the shoulder forward, and by affording increased space for the top of the shoulder blade, it favours length of this important bone. The further back the withers extend, the more do they, by giving a broad surface for attachment, indicate large development of the muscle which extends the back and loins, and the more room do they afford for the backward slope of the shoulder blade. Hence, withers which are high and which extend far back, are generally associated with a good carriage of the head and neck; free movement of the shoulder; long and sloping shoulder blades; and strength in the back and loins. Such a conformation is desirable in every kind of horse, and especially in the race-horse, hunter, and steeplechaser. Low withers, on the contrary, are usually accompanied by heavy, short and upright shoulders. Lecoq observes that
"in the mule, and especially in the ass, the withers are always low; a conformation which is in accordance with the small development of the paces of these animals." Dealers and others, when "showing off" a horse which has high withers, not unfrequently endeavour to direct attention to this fact, as a proof of the length and obliquity of the shoulders. I need hardly point out, even to the inexperienced horseman, that any particular part should be judged, if possible, on its own merits, and not by those of another part, however much excellence in the latter may indicate its possession by the former.

The Height of the Withers is, strictly speaking, that of the spines of the vertebrae of the part and the soft tissues which cover their summits. Their apparent height is the distance they project above the top of the shoulder blades; although I must confess that it is often difficult to tell how high they are in horses which have very thick withers. Animals that are comparatively high over the croup, appear to have lower withers than those which are high in front, even when we make allowance for any difference that may exist in the length of the spines themselves. The reason for this seems to be that, as elevation of the croup causes the weight of the body to be shifted forward; such a conformation tends to depress the body between the shoulder blades, and consequently reduces the distance between them and the top of the withers.

The Width of the Withers—constituting "thick withers" or "thin (lean) withers," as the case may be—depends on their apparent height; actual thickness of the spines and their cartilages; size of the muscles of the part; and the amount of loose tissue about it. Although we cannot expect leanness of withers in the cart-horse, the presence of whose massive muscles that lie between the trunk and shoulder blades, separates the ends of the latter widely asunder; still it is a very desirable point in the saddle-horse, as it indicates absence of an excess of connective tissue (p. 12), lightness of fore hand, and height of the withers themselves.
thin, high withers are objectionable; for they are liable to become hurt by a saddle, especially by a side saddle. We are all aware that when the part is of this shape, it is difficult to keep the "gullet-plate" of the saddle from touching it, however high this iron arch may be; the reason being, as far as I can see, that such a condition is usually associated, as might be expected, with emaciation of the neighbouring muscles; among the rest, that which gives rise to the prominence ("saddle muscle," see p. 183) behind the shoulder blade, and behind which the "points" of the tree of the saddle should rest. When the part is thus unduly flat, the saddle is naturally liable to slip forward. Also, with horses which have thick withers it is often difficult to keep the saddle in its place; for the presence of large shoulder muscles and abundance of connective tissue conceal the outline of the shoulder blades and render the part, upon which the points of the tree rest, smooth and flat.

"Age and sex have an equal influence on the leanness of withers, which, badly defined in the colt, come well out only towards five or six years old, at the time when the bones have attained their full length, and the body its definite size. The withers are less high in the mare than in the gelding or entire. As a set off, the last mentioned, whose fore hand acquires a considerable development, has this part thicker, especially in the case of a heavy draught animal" (Goubaux and Barrier).

As the comparative leanness or thickness of withers greatly depends on the size of the muscles of the shoulders, I shall defer the further discussion of this subject until treating on the form and function of the shoulders (p. 182, et seq.).

**Breast.**—The conformation of the breast has reference almost solely to the comparative width between the fore legs, which "is generally looked upon as a measure of the size of the chest, or, rather, of its rotundity. This is an error which we have cleared away by more than fifty observations made on the living animal, and afterwards completed on the dead
Fig. 272.—Abyssinian Ass.

Fig. 273.—Onager.
subject. We have never been able to ascertain, with respect to this point, any practical difference among animals of the same height, whatever might have been their width of breast; for the simple reason that it is not in its front part that the chest varies much, but rather in its middle and back portions. To what cause, then, other than bulging out of the anterior ribs, is width between the fore legs due? We must attribute it to the greater or less thickness of the pectoral muscles which form its base. We may see the truth of this from the fact that this part may become narrow in animals which have large chests. It is merely necessary to place them under bad sanitary conditions as regards work and feeding, to convince one that their state of emaciation brings on the loss of width of which we speak" (Goubaux and Barrier). If we take the trouble to compare the width between the fore legs of badly-shaped cart-horses which happen to be “flat-sided” and wanting in girth, with that of thoroughbreds having large capacity of chest, we shall note that the width in question bears no relation to the size of chest. Again, it is no rare occurrence to see horses that have been once broad-chested, become narrow in front when they are old and worn out. The pectoral muscles, to which the eminent French professors alluded in the foregoing extract, lie between the humerus and chest. As there is considerable lateral play between the elbows and chest of the horse; the width between the fore legs varies a good deal when the animal is standing, according as the fore feet are close together or wide apart. The fact that horses which are broad between the fore legs are very rarely good stayers at a gallop, has been used as an argument that roundness of rib is inconsistent with good breathing power. We may, however, I venture to think, account for it more correctly by saying that the failure in “staying” is owing to the undue weight of the fore hand consequent on the large muscular development of the part, and to the tendency to lateral displacement of the centre of gravity (p. 53). I must here explain that those muscles the large development of which gives increased width
between the fore legs, might with propriety be considered in conjunction with those of the shoulders (p. 182), to the bones (shoulder blade and humerus) of which they are attached at one end. The "thickness of the shoulders" is directly influenced by their development, which is naturally more or less in agreement with that of the other muscles of the shoulder. Thus we rarely see a horse wide in front which is not at the same time thick just below the withers (p. 183). As these facts are perhaps not known to the majority of readers, I have thought it well, for simplicity's sake, to discuss the respective subjects of width between the fore legs and shoulders separately. For further remarks on "thickness of shoulders," see pp. 183 and 184.

Mr. H. Wilton points out to me that horses vary very little—comparatively to their depth of body, from top of withers to brisket—in their respective "width through the heart," which is the term applied by saddlers to the horizontal and transverse measurement through the chest at the points touched by the ends of the points of the tree (supposing that they are both of full length) of a properly-made and well-fitting side saddle, when it is placed in correct position on the animal's back. The point at which the measurement is taken is indicated by the letter "d," Fig. 287. I need hardly explain that the expression "width through the heart" is not quite correct; because the heart is situated lower down, and more to the front, than the line in question. The term is, however, well understood, and serves its purpose. Mr. Wilton gives me the following average measurements "through the heart," which he has obtained during a long experience in the fitting of side saddles:—

19½ inches, for a very heavy-weight hunter (maximum).
18  "  "  15 or 16-stone hunter.
17½  "  "  13-stone hunter.
17¼  "  "  light-weight hunter, or thoroughbred.
16¼  "  "  Arab, say 14.1 or 14.2 high.

These figures certainly prove that comparative width of breast, or width between the fore legs, is not dependent, or
only to a very slight extent, on width of chest. I need hardly say that this measurement of "width through the heart" is taken behind the shoulders, the condition of which can, therefore, in no way affect it.

When a horse is narrow between the fore legs by reason of the emaciated condition of his pectoral muscles, "the keel of his breast bone becomes prominent, the points of the shoulder are pushed forward to the front, and allow to be seen, between them and the breast, two deep depressions in which the jugular grooves terminate below" (Goubaux and Barrier). These writers point to the fact that narrowness in front may therefore be either natural or acquired. In the cart-horse, width of breast is a desirable point; for he requires to have massive muscles. Close observation of thoroughbreds convinces me that a race-horse cannot be too "narrow in front;" provided that his fore legs are properly shaped and properly put on, and that the action in front is consequently "true." Undue narrowness of the chest may arise from the elbow being turned in and the toes turned out, as in Fig. 48, which represents a defective conformation of the part. The increase of width between the fore legs in proportion to weight-carrying power, is but slight in the well-shaped hunter, as we may see in Fig. 276, which is the front view of a particularly strong and active fifteen-stone hunter (Fig. 330). Fig. 277 is the front view of another powerful fifteen-stone hunter that could gallop, jump and stay with the best. We see in Fig. 275 the same view of a thoroughbred that was particularly thick, for a clean bred horse, in the shoulders and far too wide in front for galloping. The muscles of the fore arm in this figure contrast, as regards development, unfavourably with those of Fig. 276. Those of my readers who have followed me up to the present point need hardly be told that in the saddle-horse, the proportionate development of the muscles which give width between the fore legs (those of the shoulders), should never exceed that of the muscles of the fore legs. Fig. 279 gives a front view of a light harness horse which was too broad between
the fore legs for saddle work. Fig. 274 is a front view of a well-shaped race-horse which is of ordinary width between the fore legs. Sections of the chests of the horses shown in Figs. 277 and 279 are given in Fig. 286.

**Back and Loins.**—The upper line of these parts should, for beauty, run in a straight line, or with the slightest possible rise, to the croup (Figs. 9, 327, 331, 334 and 344). When the animal has a “roach-back” (Fig. 280)—that is, when this line is decidedly convex—the muscle which runs along the top of the back, and which has a powerful action on all the paces of the horse, will be found wanting in development, and the chest will, as a rule, be flat-sided. This condition of back, from the fact of its assuming, to some extent, the form of an arch, is generally supposed to be advantageous for carrying heavy burdens, as in the case of baggage animals. I am not, however, able to furnish any actual proof that such is the case. A “hollow-backed” or “saddle-backed” horse, on the contrary, is one which has this line concave, on account of the arrangement of the vertebrae of the part. It is frequently the result of relaxation of the ligaments which bind the vertebrae together, owing to the effects of hard work and debility. Thus, we may often see a horse, which in his youth had a straight back, become hollow-backed in his old age (Fig. 52). From the different position assumed by man when moving, the opposite to this occurs to ourselves. An appearance of hollow-back (Fig. 256) may be given by unusually large development of that part (*posterior iliac spine*, Fig. 12) of the pelvis which forms the highest point of the croup. I have also observed—especially among Arab ponies—the same kind of conformation arise from the pelvis being set up particularly high in animals which were low in front. No fault can be found with an apparently hollow back produced by the putting-on of the pelvis.

Without any exception, the loins and back, at the region of the cantle of the saddle, should be as flat and broad as possible; for this condition indicates the presence of powerful

Fig. 277.—Well-shaped Hunter.
rearing muscles (p. 52), and rotundity of the back ribs (p. 162). In many draught animals the upper muscles of the loins and back stand out as distinct ridges of muscle on each side of the backbone. This beauty in the coarser breeds is not confined to them, but may sometimes be seen in well-bred horses, as was the case with Mr. Kelly Maidland's Kingcraft, which was one of the best race-horses that has ever been in India. This Australian was a singularly muscular, short-backed animal, to whom distance and weight made comparatively but little difference. This "double-backed" condition may come on or disappear according to the amount of "flesh" which the animal carries. A false appearance of flatness and strength of back and loins, and of roundness of barrel, may be temporarily given by excessive fat.

In default of a generally accepted expression, I may perhaps be allowed to use the term, "wedge-shaped loins" (namely, loins which slope downwards on each side from the middle line of the back), in contradistinction to "flat loins" (Fig. 278). We must take in consideration that a wedge-shaped appearance of the loins may be caused by undue length of the spines of the vertebrae of the part, and not by deficiency of muscle, in which case the loins will be more or less roached.

**Shortness of Loins and Back.**—The appearance of comparative shortness or length which the back and loins (or back, if we include the loins in this term, see p. 20) may present, is due, I would submit, chiefly to the following causes:

1. The manner in which the croup runs into the loins. For instance, the back and loins will appear short and the croup (or "quarters") long, if the pelvis be more or less horizontal; the contour of the croup free from angularity; the muscles over the loins largely developed; and the flanks well ribbed up. We may here compare Figs. 332 and 377 with Figs. 344, 371, and Ormonde (Frontispiece).

2. The distance to which the withers run back. I may
point out that the extreme lowness of the withers in the Burchell's zebra (Fig. 258), the kiang (Fig. 384), and the onager (Fig. 273), gives the backs of these animals a false appearance of undue length. The angularity of the contour of Mike's croup (Fig. 235) might lead one to form the wrong opinion that he was long in the back and loins, if his withers did not extend so far to the rear as to counteract that impression.

3. The degree of slope of the shoulder and pelvis. It is evident that the greater the angle formed by the respective directions of the shoulder blade and pelvis produced (the more oblique the shoulder and the more horizontal the croup), the shorter will the back and loins appear to be; and vice versâ.

4. Length of neck. I need hardly say that a long neck (or a "long rein," if we include the withers) will give an air of shortness to the back and loins, and vice versâ.

5. Depth of back ribs. Compare Ormonde or Cloister (Frontispiece) with Fig. 268.

Without indulging in any tedious repetition, I think we may safely assume that, in all cases, a horse's back and loins should have the appearance of being as short as possible.

FIG. 278—SECTIONS OF LOINS

The shaded portion of this figure represents the upper part of a transverse section of the loins, just behind the cantle of the saddle, of a horse with "wedge-shaped" loins, the whole figure (namely, the shaded portion and that outside it), that of a horse with fairly flat loins.
M. H. H.

Fig. 279.—Breast of Harness Horse.

M. H. H.

Fig. 280.—Roach-Backed and Goose-Rumped Horse.

To face p. 174.
**Points of the Hips.**—When these parts are very prominent, the horse is said to have "ragged hips." Such a condition gives the animal an angular appearance, and is consequently displeasing to the eye. A horse thus formed is more likely to hurt his hips by knocking them against door-posts, or by lying on a hard surface when he is not supplied with a sufficiency of bedding, than one of different conformation. The fact of the hips of a horse being flat or ragged does not appear to influence his usefulness in any way. Among thoroughbreds, certain strains of blood have them prominent. Although it would be more correct to consider the points of the hips along with the hind limb; I have placed them, for convenience' sake, under the present heading.

**Flank.**—The only thing to remark about this part is that the "hollow of the flank," which is included between the loins, point of the hip and end of the last back rib, should be well filled up and should be as small as possible. If it is hollowed out, it will indicate that the animal is in bad health, out of condition, or of weak constitution. If the extent of the hollow of the flank be small, the animal will be well ribbed up, a form of conformation which I have discussed on p. 163, et seq. It is more essential for race-horses to be well ribbed up than for any other class; as they can ill afford to make up, by increased length and depth of chest, for any deficiency in this point. Increased depth or increased length of chest, besides adding to the weight to be carried, would militate against the possession of speed, on account of its tending to lower or bring back the centre of gravity, and thus to increase the stability of the equilibrium (p. 54).

**Croup.**—The upper line of the croup, from the loins to the root of the tail, should remain convex, even when a fairly heavy weight is carried. This convexity, more or less regular, is caused by the prominence of the inner angle of the pelvis; by the action of the muscles which flex the back; and
by the strength of the ligaments which preserve the stability of this arch. We may note how relaxation of these muscles will affect this state of convexity if we pinch the loins of a horse, so as to make him crouch, which he does by the contraction of the muscles that lie on the top of the loins. When he crouches in this manner, the upper line of the croup will tend to become straight. Hence we may accept the conclusion, which is fully borne out in practice, that undue straightness of the upper line of the croup indicates weakness of the part. I may also mention that when a horse is affected by paralysis of the muscles of the loins, the croup will usually assume an abnormally flat appearance, especially when weight is put on the back, which, in this disease, can badly support it. The slope of the croup (whether it is "goose rumped" or horizontal) will be considered on pp. 206 to 208.

**Anus.**—The anus should be prominent, and the tissues around it should be well filled out. It should be firm in appearance and closed when at rest. A hollow, flabby and open condition of the part indicates illness or general debility.

**Tail.**—The tail should be muscular at its root, and naturally short as regards its solid portion (dock). Strength of tail, as may be tested by endeavouring to lift it up with the hand under the root, usually shows vigour of body. A naturally long dock is, to a certain extent, a sign of inferior breeding.

The tail should, in all cases, be set on "high" (Fig. 281); as this form points to a more or less horizontal position of the sacrum. If this part be bent downwards, as in Fig. 280, so as to form a decided angle with the vertebrae of the loins and back, the backbone will not be as well adapted to purposes of locomotion as it would be if it were comparatively horizontal.

During movement, the tail should be carried well away
Fig. 281.—Mrs. Hayes's Arab Pony, Freddie.

Fig. 282.—Mrs. Hayes's Irish Hunter, Salary.
from the quarters; for this will indicate that its muscles are in good order. Some horses, especially those of high spirit and good blood, when going fast, carry the tail "like a flag," having the dock raised and more or less concave. It looks very bad if the tail, when carried low down, say, at the walk, has a concave bend in it, particularly if there be an abrupt turn or "kink" in the tail near its end. Such a carriage of tail is usually supposed to be associated with an "ungenerous" disposition; although this is not always the case. In coming to a decision on this subject, we should not fail to take into consideration the indications afforded by the eyes and ears. Thus, if the horse, although carrying his tail "meanly," had a "kind," fearless look about the eyes, and kept his ears well to the front, and worked them in a quick decided manner, we might reasonably conclude that the defective carriage of the tail was due to faulty conformation, and not to a sulky disposition, which would be the greater of the two evils. In making these remarks, I am, of course, alluding to horses that have not been docked.

Any unnecessary whisking of the tail when the animal is in motion is objectionable; as it is often a sign of "jadi-ness" and bad temper. We may not unfrequently remark that the fact of an animal being beaten in a race or steeple-chase is first made manifest by the tail beginning to go round and round. The swishing of the tail may here, however, be due rather to the application of the spurs or whip, than to any "unkind" running on the part of the horse. On the other hand, we may observe instances of thoroughly game race-horses, when "finishing," being so engaged in the keen struggle for victory, that they will keep the tail without movement, even under severe "punishment." Mares, as a rule, undoubtedly whisk their tails about more than horses and geldings. Some of them which are in a state of continual irritation from sexual causes, do so to an extent that is very unpleasant to their riders or drivers. Such animals are, generally, of but little use. Almost all Arab horses, and
certain horses in all countries, keep the tail rigidly fixed to one particular side, near or off, when walking, unless, indeed, to use it when occasion demands. English thoroughbreds, however, at the same pace, generally swing it from side to side in an easy, free manner, somewhat similar to that in which a fast and fair walker uses his arms when going along at, say, the rate of six miles an hour. The difference, here, seems to be due to the thoroughbred's longer stride and greater freedom of action.
CHAPTER XVIII.

THE FORE LIMB.

General View of the Fore Limb.—The term "fore limb" or "fore leg" is applied to the column of bones from the shoulder-blade to the hoof (inclusive), and the attendant soft parts. As the chief muscles of the neck are concerned in the movement of the fore limb, we must take into consideration the conformation of the former part while studying that of the latter. The shape of the muscles which lie between the upper portion of the limb (above the elbow joint) and the chest must not be neglected; for they, respectively, connect the limb to the trunk, and draw it upwards and backwards. The size of some of them, as mentioned on p. 169, regulate the width between the fore legs. As the action of the neck muscles, as regards the fore limb, has been considered in Chapters X. and XVI. (pp. 68 and 154), and that of the other muscles in Chapter IV. (pp. 31 and 32), they need not be specially noticed here. I shall now examine the nature of the work which the fore limb has got to do, with the object of drawing conclusions as to the conformation most suitable to it in particular cases. As its various parts should move in harmony together, it will at first be more profitable to study them collectively than particularly.

Chief Duties of the Fore Limb are—(1) to support weight; (2) to resist the injurious effects of "work" on its
own structures; (3) to preserve the stability of the body; (4) to propel the body forward or backward; and (5) to raise the fore hand.

To support weight, the horse requires bones and muscles strong in proportion to the nature and amount of work to be done, a more or less straight condition of the bones, and a shoulder-blade sufficiently large for the muscles which attach it to the trunk, and whose size is a measure of their strength. The comparative straightness of the column of bones will be largely affected by considerations of propulsion and of the effect of work on the legs. In all cases, the bones at the knee should be straight.

To resist the injurious effect of "work" on its structures, the bones of the shoulder and pastern (at each respective end of the limb) should be placed obliquely, if the ground be hard, so as to diminish the injurious effects of concussion, which are seen in, for instance, navicular disease, laminitis, ringbone, wind-galls, sore shins and splints. The obliquity, however, will be obtained at the expense of mechanical advantage. Hence, the softer the ground and the slower the pace; the less sloping need the shoulder and pastern be, to avoid the injurious effects of concussion.

To preserve the stability of the body, we require sloping shoulders and sloping pasterns, both of which aid in raising the fore hand. With sloping pasterns, the danger of catching the ground with the toe is reduced; for the more oblique the pastern, the easier will it be for the horse to bring his heel first on the ground at each step.

To propel the body forward to the best advantage, we require a humerus not much removed from a horizontal position; for the pushing force derived from the fore limb takes place through that bone. Also, in propulsion, the muscles which bend the fetlock joint will act best, the more upright is the pastern (p. 57). I need not say anything here about backward propulsion, as it has but little bearing on conformation. I have made some remarks on reining back in Chapter XII. (p. 99).
To raise the fore hand effectively, we require, as I have just said, obliquity of shoulder-blade and pastern, so as to favour the straightening of the limb (p. 51).

From the foregoing observations we may see that the conformation most suitable to one function of the fore limb may differ essentially from that best adapted to other offices performed by it. Consequently, the conformation to be sought for in the fore limb of a horse will be the best possible combination of somewhat conflicting elements.

Fore Legs in Saddle and Draught.—In draught, whether light or heavy, the pace is practically confined to the walk, trot, and, in rare cases, to the amble, in none of which is the function of raising the fore hand tested to anything like the same extent as in the canter, gallop, and, particularly, in jumping. Hence the saddle-horse, and especially the hunter, requires a lighter fore hand and greater power of flexing and extending the joints of the fore limb than the harness animal. Setting aside for the moment the question of the heavy cart-horse, which under all circumstances requires a maximum amount of development of bone and muscle in his limbs, we must also remember that the legs of the saddle-horse (particularly the fore ones, in proportion to the speed required) have to bear the burden of a rider, from which the limbs of the trapper are free. Consequently, the saddle-horse should have stronger legs in comparison to the weight of his body than an animal that works between the shafts, the correctness of which remark will be confirmed by an inspection of Figs. 270, 282, 324, 328, and 370, for instance. Fig. 283 shows a thoroughbred mare whose fore legs, for purposes of racing and steeplechasing, were too light for the weight of her body. She had a nice short back, powerful loins, and was well ribbed up; but, as I have already said, was too "heavily topped." Her conformation is the direct opposite of that of Specs (Fig. 255), who has a remarkably light fore hand, beautiful riding shoulders, and fore legs which have stood an extraordinary amount of work; but lacks the "close coupling"
and good loins of the mare. An inspection of the illustrations in this book, of hackneys, Cleveland bays and Yorkshire coach-horses will further elucidate my meaning. The remarks I have here made are naturally comparative, for I am of course aware that it is impossible for a harness-horse, any more than a saddle-horse, to have too good fore legs.

The Shoulder.—The degree of slope of the shoulder is difficult for inexperienced persons to determine, especially when the part is covered by fat or by thick muscles. French writers give rules for measuring with a kind of clinometer the obliquity of the shoulder-blade, which is an operation, I must confess, that I have not been able to perform satisfactorily. I have studied the subject for many years, and find that I can rely fairly well on the instruction my eyes have received during that time. The horse with the most oblique shoulders I have ever seen was St. Simon (Fig. 9), whose photograph, I regret to say, does not render this point properly, as it is a little foreshortened. The lines of his shoulder are correctly shown in Fig. 229, which is a reproduction of a painting made from a photograph that was too badly done to bear reproduction. As this illustration gives his exact outline taken in strict profile, it is valuable for comparison; although much of the detail which would have been given in a good photograph is, naturally, wanting. Ormonde (Frontispiece), Lord Arthur (Fig. 329), Midship-mite (Fig. 260), Dynamite (Fig. 237), Predominant (Fig. 236), and The Brat (Fig. 371) had very good, sloping shoulders. As instances of straight shoulders, I give Figs. 247, 280 and 284. Taking into consideration everything I have written in the present book on this point, I think we may accept the conclusion that obliquity of shoulder is a desirable point in every kind of horse, except perhaps in heavy draught animals which are not required to go out of a walk. If they have at times to exceed this pace, on hard ground, as dray horses have to do in London, they should undoubtedly have sloping
Fig. 283.—Thoroughbred Mare.

Fig. 284.—Well bred Hunter.
shoulders, so that their legs may be preserved as much as possible from the injurious effects of concussion. It is evident that cart-horses which have to labour on soft ground, like that of ordinary farms, may have with advantage more upright shoulders than those employed on road work. At the same time, even at a walk, speed, which is a desirable quality in every horse, is largely dependent on obliquity of shoulders.

The thickness of the muscles about the shoulders should be proportionate to the amount of strength which the animal may be called upon to display. We may judge it by the thickness of the structures just below (four or five inches) the highest point of the withers; by the width between the fore legs; by the thickness of the broadest part of the body at the point of the shoulders (Figs. 274 to 277); by the condition of the muscles which cover the shoulder-blade; and by the amount of depression there is immediately in front of the shoulder-blade where it joins the neck. This dip is well shown in Figs. 247, 256, and 280. The difference of level between the neck and shoulder will be best observed when the former is thin and the latter thick (see remarks on the conformation of Cloister, p. 247). At the same time, a properly shaped, heavy draught-horse will always have prominent shoulders, which in him are desirable, so as to give a broad surface for pressure against the collar.

This question of thickness or thinness of shoulders is very important, especially to hunting men, and has, up to the present, received scanty notice from writers on horses. When in the saddle we are certainly in the best position to judge whether the shoulders are thick, thin, or of medium substance. The first point that will strike the experienced horseman when mounted, is the condition of the "saddle muscle," which is the name usually given by London saddlers to the muscle close behind which, on each side, the points of the tree should rest when the saddle is on the animal's back. In a thick-shouldered horse this muscle will appear as a rounded lump at a point about 4½ inches below the top of the withers (Figs. 286 and e, 287). To explain my meaning, I have given
in Figs. 285 and 286 sections (viewed horizontally) through the shoulders of four different kinds of horses, made respectively by a transverse plane passing obliquely from the highest point of the withers through the upper part of the fore arms, so as to afford a fair idea of the contours of the shoulders at their thickest parts. The direction of this plane is shown by the dotted line a b in Fig. 287. The width of the shoulders will attain its maximum measurement at about half way down, namely at c, on the same figure. The horses represented in Figs. 274 (well-shaped thoroughbred of the 11-stone hunter class), 277 (well-shaped 15-stone hunter), and 275 (thick-shouldered thoroughbred of 13-stone hunter type), measured between the points of the shoulders (width across the breast), respectively 15, 17 and 18 inches. These photographs have been done on nearly, though not quite the same scale.

Length of shoulder-blade is a valuable “point” in all classes of horses. In the racer, considerable length of the muscles which open and close the angle made by the shoulder-blade and humerus, is conducive to speed. As the size of a bone is, as a rule, proportionate to the strength of the muscles which are attached to it; the length of the shoulder-blade may generally be taken as a measure of the strength of the muscles which connect it with the trunk, and upon which the weight-bearing powers of the animal are mainly dependent. Hence, a large shoulder-blade is not alone advantageous to the weight carrier and heavy cart-horse; but it is also essential to the jumper, in order to enable him to bear the shock of landing over a fence with a man on his back. The dog, which has a short shoulder-blade, as compared to the horse and ass, is, as we might expect, a very bad weight carrier. We may prove this practically by testing the respective strength of back of a mastiff weighing, say, ten stone, and a very small donkey, who, although he might not have as great draught power as a dog, would be able to carry far more weight.

The shoulders of the race-horse, as I have already indicated, should be long, oblique, and as light as is compatible with
their work. As far as mere speed goes, great obliquity of shoulder appears to be no advantage. As the weight is brought more forward by the shoulders being upright, than if they were sloping, the former condition, by increasing the instability of the equilibrium (p. 54), is equally, or even perhaps more conducive to speed than the latter. It also, by tending to bring the humerus into a more horizontal position, places that bone in a more advantageous direction for forward propulsion than it would have with an oblique shoulder; because the impetus given to the fore hand in progression to the front, takes place through that bone. Those particularly speedy animals, antelope and deer, have, I may mention, comparatively straight shoulders. Many of our fastest race-horses have been built in this way. It is not, however, sufficient for a horse to have the great gift of speed in order to shine on the turf; but he must also be able to "stand training," which will more or less severely test the durability of the bones, ligaments and tendons of the legs, and especially of his fore ones. Both in training and in racing, the animal has to carry a rider, whose weight will add materially to the "wear" of the fore legs, the jar on which will be far less when the shoulders are oblique than when they are comparatively upright.

Important as obliquity of the shoulders is in the race-horse, it is not nearly so much so as lightness of that part; for heaviness of the fore hand not alone throws increased strain on the fore legs, but also detracts from speed. We have three simple and practical guides by which we may judge of the lightness or heaviness of the shoulders: (1) by the manner in which the neck runs into the shoulders. If we observe that at their point of union there exists a marked depression (p. 183), we may with reason conclude that the animal, being furnished with a good surface for the collar, was evolved for draft rather than for speed. Here we must not be led astray by the appearance of any undue thickness of the neck muscles which may fill up
The full-sized figure bounded by a continued line represents a transverse section (viewed horizontally) through the shoulders of a thoroughbred with thick withers, made by a plane passing through the highest point of the withers and the fore arms. The direction of this plane is shown in Fig. 287 by the dotted line a b. The figure which is bounded by dotted lines, and which is inside the figure just described, represents a similar section through the shoulders of an ordinary well-shaped thoroughbred.
The figure bounded by a continued line (see descriptive letterpress of Fig. 285) represents a section through the shoulders of a thick-shouldered harness horse (Fig. 279); and the figure bounded by dotted lines and inside the larger figure, a section through the shoulders of a well-shaped 15-stone hunter (Fig. 277).
this dip; for the fact of their being massive would be
even more prejudicial to the galloping pretensions of the
horse than if the shoulders were somewhat "loaded." I
may point out that as the neck projects beyond the
fore legs, weight in it, by its increased leverage, will
interfere with the action of the fore limbs to a propor-
tionately greater degree than weight in the shoulders,
which will be placed more or less above this bony and
muscular spring, to which I have alluded in Chapter VIII.
(2) By the comparative width between the fore legs, which
I have discussed on page 168, et seq. (3) By the compara-
tive "thinness" or "thickness" of the withers. As a rule,
any undue thickness of the withers will be specially well
noticed, by the rider, at a point on each side, as I have
already said, about 4½ inches below the top of the withers.
This is a peculiarity of shape with which every experienced
hunting man must be familiar. A study of Figs. 285 and
286, which I drew from actual measurements, will further
elucidate my meaning.

I wish to direct special attention to the fact that
obliquity and lightness of shoulders, by tending to render the
animal's action perfect, are indispensable requisites for enabling
him to "stay" over a distance of ground. I have seen many
"sprinters" which have had upright and loaded shoulders, but
I have never known a genuine stayer—like what Ormonde,
St. Gatien, or Robert the Devil was—who had that kind of
conformation.

In the shoulders of the draught-horse we should have
plenty of power and a broad bearing surface for the collar,
into which the animal should be able to put all his weight.
It is evident that he cannot do this, if his shoulder-blades be
very oblique, which is a form aimed at by the majority of
exhibitors. Any such "show" question does not concern us
at present; for I am regarding the horse entirely from a useful
point of view. I find that the deductions I have made in this
chapter are, generally, in accordance with the experience of
practical men like Mr. G. M. Sexton, Secretary of the
English Cart-horse Society. He admires "the shoulder well let down into the chest, and with a moderate slope, it is not necessary to be too oblique, as with a hunter or a race-horse, but just sufficient to ensure free action of the fore legs, encased with plenty of muscle, which will enable him to lean into the collar. It is essential that he should be a free, fast walker. . . Action means power, time and money." Mr. F Street, in *The History of the Shire Horse*, advocates, "Shoulders well thrown back." Mr. Thomas Dykes, late Secretary of the Clydesdale Horse Society, remarks in the Stud Book of that breed, that "the shoulder should be more oblique than in the English draught-horse. This, indeed, is one of the distinctive features of the Clydesdale, as to his formation of shoulder is largely owing his long, quick step, for which he is so justly admired. The upright shoulder of the English cart-horse may certainly give greater power in the collar, but if shortness and slowness of step be considered, this cannot be called an advantage. The English horse, besides, is more accustomed to sheer dragging and to working in chains, while his Scottish rival is chiefly employed in the
two-wheeled cart, which occasions a considerable amount of weight being balanced on the animal’s back. A medium slanted shoulder gives a horse, in such circumstances, an advantage; and doubtless those who carted the minerals of Lanarkshire in ante-railroad days, found this formation well adapted for their purpose. Even yet no one will affirm that it is unsuited to the traffic of the day, if he will only take the opportunity offered for forming an opinion by the sight of the Clydesdale horses yoked to cart or lorry in the streets of Glasgow.” Mr. Reynolds, M.R.C.V.S., in his Essay on the Breeding and Management of Draught-horses, while recommending that the shoulders should be massive and well thrown outward to afford ample space for the collar, cautions his reader as follows against extreme views as to oblique shoulders:—“Many good judges insist that a cart-horse should possess very sloping shoulders. Whilst admitting the necessity of such a conformation for good saddle and light harness horses, and appreciating its beauty in heavy animals, I am decidedly opposed to the opinion, on the ground that such a form is almost invariably associated with thin withers and shoulder-blades closely applied to the front ribs, affording an insufficient and insecure seat for the collar, and, consequently, one very defective for the purposes of heavy draught.”

Horses—like the heavy draught animals of Edinburgh, Liverpool and Manchester—that have toe-pieces on their shoes, and consequently make full use of their fore legs as propellers, should, for this object, have fairly upright shoulders, and should have no bearing-reins, which would impede them in advancing and lowering their heads. Dray-horses, like those in London, which have flat shoes in front, should have sloping shoulders. I may, therefore, venture to settle this question by saying that heavy cart-horses which are not required to go out of a walk, and which, in order to perform their work to the best possible advantage, ought to have toe-pieces, should have upright shoulders; and that those which have to trot as well as to walk, should have sloping ones. If
the ground, such as wood pavement or asphalte, be unsuitable to the use of toe-pieces, the animals, even if they have not to go out of a walk, should have oblique shoulders; because in this case the fore legs will be concerned more in maintaining the stability of the body than in propelling it. We may also infer that horses which have toe-pieces on their fore shoes, will do their work best when their shoulders are upright.

The shoulders of the hack and light harness horse ought to be oblique and light in order to obtain sure-footedness, good forward reach, and sufficient knee action. Although the match trotter should be built more or less like a race-horse, it is even more necessary for his shoulders to be sloping than for those of the galloper; because, unless they are so, he cannot have free knee action. I may mention that the fast trotter requires to be able to bend his knees a good deal more than the race-horse.

The shoulder-blades of the hunter and chaser, as I have before said, should be long and oblique, so as to enable him, in the best possible manner, to resist the shock of landing over a fence. On account of having this special kind of work to do, his shoulders should be more muscular than those of the race-horse. The fact of his shoulders being sloping, will enable him to "take off" more cleverly at any obstacle than he could do, were they upright.

The term "good shoulders" or "bad shoulders" is nearly always a comparative one; for shoulders which might be very bad in one type of horse, might be very good in another type; and vice versâ. Besides, we rarely see shoulders which would be unsuitable for any class of work, supposing, of course, that the other parts of the body were of appropriate conformation.

The Humerus.—The position and form of this bone, which lies between the shoulder joint and elbow, are so hidden by the muscles about it, that it is difficult to form a correct opinion as to its conformation. Even if it were exposed to
view as much as is the fore arm, I cannot see how the fact of its being so, would greatly help us. We know that forward propulsion given by the fore limb must take place through it; but I cannot say exactly what is its best direction for purposes of progression. We are aware that the different paces of the horse require, in varying proportions, the direction of the propulsion to be both upward and forward; but we cannot tell what these proportions should be. It is evident that the heavy cart-horse, which requires the aid of his fore limbs to propel him forward, should not have an upright humerus. It appears probable that the angle which the shoulder-blade makes with the humerus, varies but little in different horses; in which case, the more oblique the shoulder-blade, the more upright the humerus, and vice versa. Consequently, by observing the slope of the shoulder, we might estimate that of the humerus.

Elbow.—The point of the elbow should be capable of being drawn well away from the side. It will then have plenty of freedom, and will not be tied down to the chest.

Fore Arm.—This part in all horses should be muscular; as its muscles have to do all the work of the limb below the elbow. On p. 138, I have alluded to its comparative length. In Figs. 322, 324, 329, 332, 333, and 370, are shown well-shaped fore arms; in Figs. 304, 305, and 310, mean ones. Although a race-horse might have a somewhat light fore arm without much detriment, it is imperative for the jumper to be strong in this part; for in leaping great strain falls on the muscles at the back of the fore arm in straightening the fetlock, by which action the fore hand is raised. It goes almost without saying that the heavy cart-horse should have a powerful fore arm.

Castors or chesnuts.—On the fore arm, generally, but not always, nearer the knee than the elbow, there is a horny growth, called a castor, corn, or chesnut. It is generally flat, and more or less in the form of an oval, the greater diameter
of which is about two inches in length. It may, however, take the form of a small horn (Fig. 291), in which case, it will, as a rule, readily break off from its base, if force be applied to it. Goubaux and Barrier state, as an extremely rare occurrence, that absence of castors from the fore legs has been observed in horses. There are, in almost all cases, similar, though somewhat smaller, castors on the inside of the hind limbs, just below the hock and near the back of the leg. Huzard, and Goubaux and Barrier remark that they have seen instances of the hind castors being absent in the horse. They are larger and of a more horny texture in coarse-bred horses than in blood animals. Nothing is known of the origin of castors (p. 274).

Knee.—Looking at the knee in profile, while the horse bears weight on the leg, we should find that the cannon-bone and radius are nearly in a straight line. In reality they are not quite so in perfect specimens; but are united by a slightly undulating line of great beauty, the contour of which I am unable to lay down with mathematical accuracy. Figs. 255, 256, 282, 294, 322, 324 and 332 furnish us with good illustrations of well-set-on fore arms, knees, and cannon-bones. Fig. 299 is an example of the condition known as "calf-knees," to which there is a slight tendency in Figs. 297 and 306. The opposite formation ("being over at the knees") is shown in Fig. 303, to which there is an inclination in Fig. 304. This condition is generally due to hard work; but may, I am inclined to think, be natural; for I have seen it in young animals which had not been broken in, and which had consequently done no work, beyond voluntary exercise in their paddock. I may hazard the conjecture that purely congenital "standing over at the knees"—as, probably, in Fig. 303, which represents the fore legs of a four-year-old well-bred hunter type of horse which had done very little work—will be unaccompanied by alteration in the slope of the pastern. As a great rule, when a horse stands over at the knees from
work (Fig. 259), the pasterns become abnormally upright. The horse whose fore legs are shown in Fig. 303 had unusually sloping pasterns.

The fact of a horse being "calf-kneed" renders the back tendons and check ligaments more liable to sprain by violent descent of the fetlock than if the knee were straight. It tends, however, to make the animal more sure-footed, by bringing the weight back from the toe. In all cases this condition adds to the tension to which the back tendons are put when they are flexing the foot. Although it is in no way an advantage; it is much less a detriment to the cart-horse, which has rarely to go out of a walk or slow trot, than to the saddle horse or fast trapper. Many heavy cart-horses are "back at the knees" (Fig. 232), which is a shape of the fore limbs that is not uncommon among Arab and East Indian horses.

As the bones of the knee give attachment to important tendons and ligaments, and as other important tendons, respectively, pass over the front and rear aspects of that joint; it is a beauty, recognised by all good judges, for the horse to have broad, large knees, as viewed from the front. The front surface of the knee should also be flat (Fig. 298); for any prominence of the part, as in the case of a "big" knee, will point to the probability of unsoundness, which is, however, a subject outside the scope of this book.

From Knee to Fetlock.—We know from experience that the more nearly parallel the back tendons are to the cannon-bone—other things being equal—the better able will the limb be to stand work. Why this should be the case I cannot say with certainty. I may, however, hazard the conjecture that, as "tying-in" below the knee is due to the smallness of the bones which form the groove through which the back tendons pass, this condition may point to want of size in these tendons; for "the function makes the organ." It appears that the calibre of this groove (or rather canal), which, to a great extent, is formed by the trapezium, is, as a rule,
M. H. H.

Fig. 291.—Long Castor on hind leg.
ample for the working of these tendons; for when such "tied-in" tendons happen to become damaged by work, the seat of injury is very rarely behind the knee. Hence I think we may conclude that when this groove—which is dependent for its size on that of the bones behind the knee—is comparatively small, the tendons are also proportionately wanting in substance, and consequently unduly weak. I have always remarked that, in legs of about the same size of cannon-bone, when the back tendons approached a direction parallel to the cannon-bone (as in Figs. 270, 292 to 295, 296 and 298), they were larger and consequently stronger than those which were tied-in (as in Figs. 300 and 302). The parallelism of the back tendons with the cannon-bone is beautifully shown in Fig. 293, which represents the fore legs of a thoroughbred yearling filly. We should, I may observe, regard a large degree of backward projection in the trapezium as a desirable "point"; not merely as indicating the size of the bone itself, but also that of the other bones of the knee. The trapezium is well developed in Figs. 292 to 295, 298, 299, and many of the other photographs in this book; and poorly, in Figs. 300, 301, etc.

The objectionable tying-in of the knee, which we may see in Figs. 297, 300, and 302, is, I believe, due in almost all cases to an admixture of more or less cart blood. Although individuals of other breeds may be light below the knee, I have never seen in them this fault emphasised by undue width of pastern (from front to rear), in the same manner as it is in the draught animal of Western Europe. Experience tells us that a leg which shows the form of tying-in below the knee to which I allude, is altogether unfit for fast work, or for jumping, and is unobjectionable only for labour which does not require the animal to go quicker than an ordinary trot. The reason for this is, as far as I can see, that a large fetlock is characteristic of cart blood, and consequently indicates that the bones of the part are unfitted for work at fast paces. As bones are subordinate to muscles, we may take for
196

THE FORE LIMB

granted that, if the former be weak in structure, the latter, as well as the tendons and ligaments, will also be wanting in strength. Eastern horses, and those of Oriental blood, are often very light below the knee, but they hardly ever possess undue width of fetlock. A thoroughly sound rule, which is borne out in practice as well as by theory, is to judge (as regards this particular point) the wear-resisting powers of a fore leg by the direction which the back tendons make with the cannon-bone, and not by its measurement below the knee, which is worthless, unless that round the fetlock is also taken into consideration. It is important to note the difference between a leg which is light below the knee, and one which is tied-in below the knee. The latter is always objectionable; the former, only when the body is too heavy for the fore legs, as in Fig. 308.

The desirable condition of comparative shortness of cannon-bone is, I think, more frequently seen in hunters, than among other classes of horses. It is well shown in Fig. 320.

With respect to knees being "well let down," see p. 212.

The cannon-bone should be of good substance, as in Frontispiece and Figs. 294, 298 and 328. It should feel hard to the touch and free from any excess of soft tissue between it and the skin, or from enlargement from the effects of work or disease—any one of which conditions would give it an appearance of undue roundness. The back tendons, as I have just pointed out, should be as nearly as possible parallel with the cannon-bone. They should be straight, and hard as if they were made of catgut, and in well-bred horses with fine skins, the division between the two tendons should be visible on close inspection. Any deviation out of the straight line, or any fulness or softness, will indicate the presence or previous existence in them of injury or disease. If the leg be free from an excess of hair, the suspensory ligament should stand out in bold relief (Fig. 292) between the cannon-bone and back tendons, and should feel as tense and hard as a fiddle-
Fig. 292.—Clean Fore Legs.

Fig. 293.—Good Fore Legs of Yearling Filly.

Fig. 294.—Good Fore Legs of Hunter.

Fig. 295.—Good Fore Legs of Well-bred Horse.
if there be any difficulty in tracing its course with
the fingers, or if it feels soft or rounded, we may rest
assured that it has suffered from injury, which fact will
probably prevent it from standing much work. In "clean"
legs (Fig. 292), we should be able to trace the course of
the suspensory ligament for some distance on each side,
as it proceeds obliquely down the pastern.

**Fetlock.**—The chief points about this joint are: that it
should be flat from side to side, and that, viewing the leg in
profile, it should not (as I have previously remarked) be
broad as compared to the width of the leg just below the
knee (Fig. 297). Any roundness of the fetlock, which will
be caused by undue thickness from side to side of this
part, will indicate the effects of "work," or of injury. The
peculiar roundness of fetlock, caused by sprain of the
suspensoiy ligament at its attachment to the sesamoid bones,
will be readily noticed by the practised observer.

At the back of the fetlock there is a lock of hair which
gives its name ("feet-lock") to that joint, and which is par-
ticularly abundant in cart-horses. This tuft of hair covers
a fatty mass (the fetlock pad), and has in its centre a
horny growth, called the **ergot.**

**Pastern.**—By the working of the fetlock and pastern
joints, the injurious effects, on the limbs, of concussion are
more or less obviated, and assistance is given in the straight-
ening of the limb, to raise the fore hand. As the horse will
have no difficulty, under ordinary conditions of soundness and
labour, in bringing his pastern into the same straight line as
his cannon-bone; the amount of "play" which the fetlock
will have, will depend on the distance through which the
fetlock can descend, or, in other words, on the acuteness of
the angle which the pastern can make with the ground, when
weight is thrown on the part. Although we cannot, by mere
inspection of the animal, determine the efficient limit of this
angle, we may assume that horses which have, when standing,
what are called sloping pasterns (Fig. 298), will have more play in these joints than those that have upright pasterns. On the other hand, their back tendons and suspensory ligaments will work at a greater mechanical disadvantage. As the expressions "oblique (or sloping) pasterns," and "upright pasterns," are more comparative than absolute, it is impossible to define them with precision. Figs. 298 and 306 may be taken as good examples of these respective forms of conformation. I need hardly say that pasterns which would be far too upright for fast work on hard ground, might do admirably on soft ground or for slow draught. Although the pasterns of the fore legs shown in Fig. 306, appear very upright; they belonged to a horse that galloped in good style, and jumped (Figs. 195 to 199) with great cleverness and flippancy, on all kinds of ground. The abnormal upright-ness of his pasterns when he was standing, in no way prevented his fetlock and pastern joints from having free play during movement. The obvious lesson here is that shape should not be studied independently of action. We may accept, as an axiom, the statement that the harder the ground and the faster the work, the more sloping should the pasterns be, in order to save the legs from the injurious effects of concussion (p. 57). If the horse be required to gallop over hard ground, the pasterns can hardly be too oblique (supposing, of course, that this condition has not been brought on by injury); provided always that the pastern bones are strong. I may point to Fig. 298 as an extreme case of sloping pasterns in an Arab horse that had remarkably sound legs. I may mention that such instances are in no way uncommon among the sons of the desert; and that, as a rule, the possessors of such pasterns are animals which like to "hear their feet rattle." As a case in point, I may instance Mr. Covey's famous Arab, Marquis, who won all over India, at all weights and all distances (in his own class, of course). After doing as much work as would break down a dozen ordinary horses, his legs were as clean as when he was foaled, although, even when walking, his fetlocks

To face p. 198.
came nearly down to the ground at each step—so oblique were his pasterns. Their bones, though long and sloping, were, however, of good substance. My experience among horses in many lands leads me to the conclusion that the drier the country in which they are bred and reared, the more sloping are their pasterns. I advance no theory in support of this instance of the "survival of the fittest," which I give merely for what it is worth. Australian horses, I may mention, have their pasterns more oblique than English horses (though practically of the same blood), and are consequently better fitted for work on hard ground. As the shoulder-blade and pastern are at the opposite ends of the spring made by the bones of the fore limb, we may infer that they should be more or less at the same slope. Hence, if it be desirable that a horse should have oblique shoulders, he should also have well sloped pasterns, which is a term that had best be accepted as indicating a condition of limb, in which the fetlock and pastern joints have free play.

The two curses which remain on English thoroughbreds are upright pasterns and roaring. The former condition is such a common defect that it generally passes without notice, and is accepted by the ignorant as the proper kind of conformation. Of the two, I certainly think that undue straightness of pastern is the cause of the turf career of more English horses being cut short than is roaring. Examples of this fatal shape are but too common.

As I have already said, the defect of uprightness of pastern in the fore limb (want of "play" in the joints of the fetlock and pastern), not alone militates against the speed of a horse by causing him to suffer to an undue extent from the injurious effects of concussion; but also tends to decrease his power of raising his fore hand by the straightening of the fore limb, as we see done in Figs. 128, 129, 130, and 131. It is evident that when the fetlock and pastern joints possess but little mobility, there will be only a slight descent of the fetlock joint, and consequently their "play" will affect but
little the length of the limb. I may here repeat (p. 47) that propulsion is accomplished by the straightening out of the limb, to effectually do which, the joints in question must possess the ability to be freely flexed and extended. Every experienced trainer will have noticed that as a race-horse's fore pasterns become more and more upright from work, the more will he lose his speed and his "level" style of galloping. This will also occur to a horse whose pasterns have become abnormally oblique on account of sprain of the suspensory ligament, in which case the defect will lie in the inability to straighten the joint freely when weight is thrown on the limb. It is evident that the longer the pastern, the greater will be the play of the fetlock joint. Hence, length, as well as obliquity, of pastern is an indication of speed.

Polo has done much to teach men in England the necessity of sloping pasterns for work on hard ground.

Lecoq remarks that: "The direction of the pastern is almost always influenced by its length. The shorter the pastern, the more upright is it; and the longer it is, the more is it sloped." This rule may hold good in horses of the same class; but not, at least to the same extent, among animals of different breeds. This French writer also adds with justice that: "There are, however, horses—and especially mules and asses—in which the pastern, although very short, is well sloped." As the evil effects of concussion fall much more severely on the fore limb than on the hind leg, its pastern is, normally, more sloping.

Referring to Clydesdales, Mr. Dykes writes: "No doubt the upright pastern suits well the upright shoulder and slow action of the English draught-horse, a conformation which can scarcely be called the best for any purpose; but it will not do in the Clydesdale, which requires a pastern to suit the formation of the shoulder, and to confer the necessary elasticity to counteract the concussion caused by his quick firm step. Short upright pasterns always get worse with age and feeding, and the action in due course of time becomes impeded. A horse with an upright pastern has little or no

command of his foot, and literally walks as on a crutch; and if he has no power of his foot, he cannot have much in his shoulder. The streets of Glasgow are very trying to horses which have to scramble for a footing in the furrows between the hard, smooth paving stones; and horses with upright pasterns are sometimes almost powerless to move, where those with pasterns moderately sloped, and of medium length, can walk with comparative ease. Farmers around Glasgow are alive to this, and will not readily use a stallion which has this defect, however strong and shapely.” The comparisons which Mr. Dykes draws between the Clydesdale and the Shire horse in no way concern us here.

The Hoof.—The hoof serves as a horny boot in which to enclose the bones and soft structures of the foot. The horn of the wall, sole, and frog should be thick, hard and tough, so as to resist in an efficient manner the effects of wear. Moisture has a well-marked softening and weakening influence on the horn, and it consequently affects the form of the foot. We shall find that the drier the climate; the stronger is the horn of horses reared in it; the more upright are the feet; and the more concave are the soles. I may explain that when the horn of the wall and sole is weak, it will not be able to efficiently support the weight thrown on the leg, and the foot will have a tendency to become flat. The feet of, for instance, horses bred in Australia are stronger than those produced in England, owing to the climate being drier; although both are practically of the same blood. The fact that water mechanically softens horn, does not explain why the hoofs of horses in damp climates should be produced thinner than those of animals in dry climates. We know from experience, however, that moisture has a great influence in quickening the growth of horn, as we may see in horses turned out on marshy ground. Also, in those parts of India where the yearly rain-fall, though large in quantity, is practically confined to about four consecutive months, it is found that the growth of the horses' feet during the "monsoons" is much
greater than it is in the dry weather. Hence, we may reasonably conclude that this stimulation in growth is one of length of horn, and not one of increased horny material. The case, I submit, is somewhat analogous to that of plants, which, under the influence of an excess of moisture, spring up quickly, with tissues full of water, but with little solid matter. The great trouble with heavy cart-horses in England is from the weakness of their hoofs, the horn of which, as a rule, is neither thicker nor stronger than that of well-bred horses; although the strain which falls on it is much greater than that which tries the tenacity of the horn of the feet of saddle horses. Considering the greater size of the muscles and bones of the draught animal, we should expect that the horn of his hoofs would be proportionately stronger than that of the half-bred. The fact that it is not stronger, is a proof that English cart-horses are deficient in one of the most important points of usefulness. Veterinary surgeons in practice in England and Scotland could tell us that the large majority (I would say about nine-tenths) of cart-horses which come to them for treatment, are foot cases. The ideal hoof of a cart-horse should in no way differ from that which is most suitable to a light trapper, hunter, or race-horse, except that it should be larger and consequently stronger. Therefore, we should regard with disfavour the weak feet, with their low, spread-out heels and flat soles, which, from their frequent occurrence, have become too generally accepted as characteristic of cart-horses. Small contracted feet are equally bad.

The inner quarter of the foot is more upright than the outer quarter, and its ground surface is straighter; conditions which provide for the fact of more weight falling on the inner than on the outer part of the foot. The horn has its maximum amount of thickness at the toe (at which part there is the greatest amount of wear from friction with the ground), and gradually gets thinner as it approaches the heels. As the fore feet are intended to support more weight than the hind feet; their ground surface is broader, their frogs are larger, and their heels are lower.
Fig. 304.—Slightly over at the knees.

Fig. 305.—Bones of pasterns too slight.

Fig. 306.—Upright pasterns.
From many careful measurements of well-formed feet, both in a natural state and when subjected to the influence of shoeing, I have come to the conclusion that the slope of the fore foot, at the toe, should be about 50°, with a variation, one way or the other, of, say, not more than 3°. The slope of the hoof will conform somewhat to that of the pastern. The outside surface of the hoof should be naturally smooth, and should be straight from the coronet to the ground; for undue roughness, bulging-out, or concavity of surface will probably indicate the presence or previous existence of disease. The heels should be strong and the "bars" well developed, so that the proper slope of the foot may be maintained, and that the liability to "corns" or to contraction of the heels, may be lessened. I may point out that one effect of shoeing in the ordinary manner is to cause the heels to be subjected to more wear than the toes; for, at the latter part, the position of the iron with regard to the wall is fixed; but at the former there is a certain amount of "play" between the shoe and the horn. Consequently, the tendency of the shod foot will be to acquire a less slope than it ought to have at the toe. This difficulty in preserving the proper shape of the hoof is a troublesome one to every careful and competent shoeing smith. Some horses have such weak heels, that if they wear ordinary shoes, it is impossible to keep the feet at a proper slope, or to prevent them getting corns. The fact of the feet being at a less slope than natural, will cause an undue amount of strain to be thrown on the back tendons (p. 57). I may mention that if the bars be weak in proportion to the wall, or if they be cut away, the heels of the shod foot will have a tendency to contract. Unusual width between the heels is generally associated with weakness of those parts. At the same time they should have no tendency to contraction, which will not be present if the frog, as it ought to be, is well developed. I may remark that an abnormal size of frog, especially if the sole be convex, or even flat, will, as a rule, point to the effects of laminitis (fever of the feet). If, however, the frog is in a healthy state, and if the sole, as it
should be, is concave in form, the observer need not fear that the frog is too big. Horses which have never been shod, have their frogs much larger, their heels further apart, and the ground surface of their feet of greater area, than those which habitually stand on iron. The cleft of the frog in a healthy foot is merely a slight depression in the centre of the frog, and does not communicate with the sensitive structures immediately above the frog. If the wall be strong and the sole be concave, we may rest assured that the horn which covers the sole is of sufficient substance, provided, of course, that it has not been pared away by the shoeing-smith. Some horses have an excess of soft tissue at the back of the foot, which then makes the distance between the coronet and heels abnormally long. This condition is known as "boxy" or "fleshy heels," and is objectionable in that it cramps the action of the foot, and renders it weaker, and consequently more liable to injury, than if the foot were in a normal state.

An undesirable kind of conformation (Fig. 305) which is sometimes seen, usually in horses that have a combination of cart and thoroughbred blood, is that which gives the hoof the appearance of being too big for the bones which it covers, without being in any way deformed by disease, or by an overgrowth of horn. This condition is due to the pastern bones being slight in comparison to the size of the pedal bone, which, in health, regulates that of the hoof. In such cases, the leg is not alone abnormally weak, but the fact that its bones are not symmetrical, points to the probability that there are, in other parts of the framework, similar instances of lack of harmonious conformation.

CHAPTER XIX.

THE HIND LIMB.

General View of the Hind Limb—The Pelvis—Thigh and Stiffe—Tibia—Hock—Cannon and Fetlock—Pastern and Hoof.

As many points of resemblance exist between the fore and hind limb, I shall assume, in order to avoid needless repetition, that my readers, before arriving at this chapter, have studied the preceding one, and also Chapter VIII., in which I have tried to explain the action of both pairs of legs.

**General View of the Hind Limb.**—As the pelvis, which is analogous to the shoulder-blade of the fore leg, is essentially a portion of the hind-quarters, I have reserved its consideration for this chapter, instead of the one (Chapter XVII.) in which I have attempted to treat of the trunk. Although the chief function of the hind limb is that of propulsion, it has, like the fore extremity, to bear weight; but to a lesser extent, and is also less exposed to the effects of concussion. Thus we see that while the shoulder-blade is connected to the body by muscles which work like a spring, in order to save the parts from the ill effects of concussion; the pelvis is firmly united to the spine, so that the force of propulsion by the hind limbs may be transmitted to the body with but little mechanical loss. The pastern and hoof of the hind-quarters are naturally more upright than those of the fore hand, and, con-
sequently, the muscles which bend them, act to greater mechanical advantage.

We have seen in Chapter VIII., that for the attainment of high speed, the horse should possess the fullest ability to bend and extend the hind limb. Hence the beauty, in the race-horse, of a "straight dropped" hind leg. As this power chiefly depends on the action of the hock, I shall defer its further consideration, until I come to that joint.

On page 138, I have remarked that the desirable proportions for the bones of the limb are: pelvis, long; thigh, short; tibia (from stifle to hock), long; cannon, short; and pastern, long.

The sets of muscles which move the joints of the hind limb, appear to complete their respective actions, in succession, from above downwards, namely: the hip-joint first; then the stifle; and, finally, the hock and fetlock; the former being extended by the muscle that bends the latter. We may infer that, to be effective in the production of speed, these actions must increase in rapidity in the same order. As the muscles that "start" the weight at each step are those which extend the hip-joint, we must look for, in the cart-horse, special muscular development of the croup and thigh. In the race-horse, however, length and power of the muscles of the gaskin, which cause acceleration of speed at the end of the "stroke," should be particularly sought for. These deductions, I may remark, are in accordance with the nature of the conformation respectively exhibited by horses which are the representative types of the two classes.

The Pelvis.—For speed we require the pelvis to be as long as possible; for strength, as broad as it can be.

The consideration of the best slope for the pelvis is a much more difficult question than that of the most suitable angle for the shoulder-blade, which, for most purposes, cannot be too oblique.

If we examine Fig. 94, and refer to Chapter IX., we shall see that the push, in draught, by the hind leg, is in an irregular
line from the toe, through the bones of the hind limb, the pelvis, and the body, to the centre of pressure of the collar on the shoulder. In Fig. 139, the line of propulsion is similar to that in heavy draught, except that it passes through the centre of gravity, instead of the centre of pressure on the shoulder by the collar. It is evident that the straighter, or less convex, this irregular line is, the more effective will be the propulsion. In draught, therefore, shortness of the hind limbs, as compared to the fore hand, will be an advantage (as I have also pointed out on p. 61), in that it will tend to render the line of bones through which propulsion takes place, straight. As good length of hind limb is a necessity in the galloper; any reduction in the convexity of this line will have to be obtained by the opening out of its angles, and not by curtailing the length of the hind limb. Thus, the hind leg will be stretched out as much as possible to the rear (compare Figs. 94 and 139), and the direction of the pelvis (as a point of conformation) will be more horizontal than in the draught animal. The so-called horizontal croup is not alone a great beauty in the saddle horse, but it is also a decided mark of speed. If the pelvis or croup (which in this case is practically the same thing) be too level (pp. 175 and 176), we may suspect that the back is weak.

I need hardly point out that the pelvis is more upright when the animal is standing still, than when he is in movement; and when he has no burden on his back, than when he is mounted.

In jumping, the conditions are different from those of galloping or draught; for special provision has to be made in the leap for raising the fore hand when the horse "takes off." If we refer to Fig. 195, we shall see that the more a horse, at that moment, gets his hind legs under him, the easier will it be for him to raise his fore hand. The more sloping is the conformation of the pelvis, the more will the hip joints be lowered and brought forward. Hence a "goose-rumped" horse will be able to get his hind legs more under him, than if his pelvis were more or less horizontal. The
correctness of this theory is borne out by the fact that in Ireland hunting men like a hunter to have a drooping pelvis, because, so they say, this shape is generally associated with cleverness in jumping. Although high-class chasers generally have the pelvis fairly sloped; they are rarely goose-rumped, with an exception now and then, like Soarer.

From a galloping point of view, a drooping pelvis is a serious defect; for its existence implies that the backward sweep of the hind leg is proportionately curtailed, and consequently the compass of the stride is more or less cramped. Also, on account of the point of the buttock being depressed, the muscles (the *ischio tibial*) which are attached to it and to the head of the tibia, and which aid in the extension of the hip-joint, will be unduly shortened in length. To have the point of the buttock placed high and projecting well to the rear is a great beauty, which may be seen in some thoroughbreds and high-caste Arabs. I may state that this kind of conformation is found in a high state of perfection in the hare, in which animal the pelvis is not alone more or less horizontally placed; but the portion of it (the *ischium*) that is behind the cavity in which the head of the hip-bone works, is much longer in proportion to the remainder of the pelvis than it is in the horse.

A horse with unusually drooping quarters, as in Fig. 280, is said to be "goose-rumped."

The prominence which some horses show in the middle of the croup (Fig. 235), is due to the large development of the inner angle (posterior iliac spine, Fig. 12) of the pelvis (at each side), and points to the presence, in the part, of strong muscles. Cloister (Frontispiece) and St. Gatien have this prominence well marked. This peculiarity indicates great length of pelvis, which is a very desirable point in the hunter and chaser, in both of which, as we have already seen (p. 184), a long shoulder-blade is essential. As the pelvis in the hind limb is the analogue of the shoulder-blade of the fore limb; it follows that these two bones should be of proportionate length.
**Fig. 309.**—A Finish at Kempton Park.

**Fig. 310.**—Upright Shoulders and Poor Gaskins.
Thigh and Stifle.—The muscles of the thigh should be well developed, so that, when viewed from the rear (Fig. 287), they should leave no unsightly gap between the legs. For speed, the thigh should be comparatively short (p. 138), in which case the stifle will have the appearance of being placed high up on the flank (p. 139). The stifle should be directed well outwards, so that it will have no difficulty in clearing the abdomen, which the peculiar construction of the hock joint that is explained on p. 58, enables it to do. It seems probable that the fact of some "cow-hocked" (hocks turned in, p. 210) horses being able to show an unexpected turn of speed, is frequently due to this kind of conformation conferring on them increased ability to bring their hind feet well forward.

Tibia.—Under this term, I wish to include the muscles and tendons between the stifle and point of the hock, with their coverings, as well as the tibia (Fig. 12), which, I may repeat, is the bone that lies between the stifle and hock joint. For speed, the tibia should have a maximum of length (p. 138). It is very long in the hare.

The Gaskin is one of the most important points by which we may judge of the suitability of a horse for fast work; for I venture to assert, after a long and careful study of the subject, that it is impossible for a horse to have a really fine turn of speed, unless he has broad gaskins. I may point out that width of gaskin is conferred by length of os calcis (p. 26). We may see from p. 58 that the longer the os calcis, the greater is the mechanical advantage at which the muscles that are attached to the point of the hock, work. I may add, that these muscles agree in length with the tibia, and that the longer they are, the quicker will be the action of the hock in propulsion. The gaskin should not alone be broad, for purposes of speed; but in all cases its muscles should be well developed (Frontispiece and Figs. 274, 312, 320, 322 and 370). In Fig. 310, the gaskin is poor.
The Hock.—On page 64, I have indicated the direction which the hock should have, as viewed from behind. We have seen on page 58, that by a special arrangement of the bones of the hock, the stifle is enabled to clear the abdomen, without altering the direction of the hind foot, when the hind leg is brought forward during movement. This action is facilitated by the fact that, in a normally shaped leg, the hock is directed slightly outwards as well as forwards. When the points of the hocks are turned in to excess (Fig. 50), the effect on the eye is bad, but the mechanical loss is small, unless, indeed, the fault be much exaggerated. If, on the contrary, the points of the hocks be turned outwards, the forward reach of the hind legs will be impeded by the abdomen. Also, if we observe, from behind, a horse which has this kind of conformation, and which is walking, we shall as a rule find that each hock, instead of moving steadily in a straight line, receives a peculiar twist (which must be accompanied by loss of power) while it is propelling the body forward. Experience certainly teaches us that, of the two defects, it is better for a horse to have his hocks turned in, than to have them turned out.

For purposes of speed, the hock should possess the power of being fully extended (p. 51), hence the beauty of a "straight dropped" hind leg. In all great gallopers (Ormonde, Cloister, St. Simon, Favonius, and Persimmon) we may see this kind of conformation; although it is true that some fairly speedy horses (but not of the highest class) have their hocks more bent than the types I have given. This ability to straighten the hock is not required, to any great degree, in animals that are used at slow paces. "Sickle-hocks" (Fig. 316), as those are termed which remain bent to a marked degree, when the joint is extended as much as possible, are, however, objectionable in any kind of horse.

While recognising the desirability of straight hocks for speed, we must not forget that this kind of conformation, to be effective, must be accompanied by good length of hind limb from hip-joint to foot, in order to obtain full advantage

from flexion and extension. If the hind leg be comparatively short and the hock straight, as in Fig. 280, it is evident that there will be but little straightening out of the limb, when the "shove-off" is being given.

The width of the leg, immediately below the hock (looking at the limb in profile), should be as great as possible compared to the width of the fetlock. This desirable shape (which has its analogy in the fore limb, see p. 195) is well shown in Figs. 311, 313, and 314. I may remark that the hock in Fig. 314, which is that of a half-bred saddle nag, is not a particularly straight one, although it is otherwise well shaped. Fig. 317 is a capital illustration of the defect known as "tied-in" below the hock. Fig. 311 shows a beautiful hock—with great bone and straight-dropped hind leg—of a smart and strong hurdle racer and chaser (Mariner by Geologist). We may contrast it very favourably with the hock in Fig. 319. The hock (that of a thoroughbred) in Fig. 318, though fairly good, is neither so straight nor has such good bone just below the joint as that in Fig. 311. The leg in Fig. 312 belonged to a yearling thoroughbred, by Highland Chief, that had, as we may see from the photograph, remarkably good hocks for her age.

We are all agreed that a horse should have large hocks, an expression which—granting that its shape is good in other respects—is synonymous with "strong hocks." If we find that a horse is not "tied-in" below the hock, and that his gaskins are broad (i.e. his os calcis long), we may rest assured that his hocks are of good size.

As the diseases and injuries of the hock belong to the domain of equine surgery, and as I have investigated them in *Veterinary Notes for Horse-owners*, I shall not allude further to them here. The desirable absence of synovial enlargements and of an undue amount of cellular tissue will be indicated by the bones, tendons, and ligaments, and by the hollows and eminences formed by them, being clearly defined underneath the skin.

The horse has on the inside of each hind limb, and a little
below the hock joint, a castor or chesnut somewhat similar to that found in the fore leg (p. 192).

_Hocks and Knees well let down._—There is no point in the conformation of the horse, upon which more stress is usually laid, than that which may be described in horsey language as "hocks and knees well let down," or "hocks and knees close to the ground." The cheetah (Fig. 3) has this point well marked. The black buck (Fig. 1), another speedy animal, is, on the contrary, long from his hocks and knees. From an examination of the comparative length of the bones of the limbs (pp. 137 to 139), we know that the proportion of the length of the column of bones below the knee and hock to that of the radius and tibia, respectively, remains more or less constant. How then comes it, we may well ask, that the idea of the hocks and knees of some horses being better "let down," than those of other horses, has gained currency? As regards the fore limb, the answer is easy; for the knee of a leg which has a comparatively short cannon-bone and a sloping pastern, would, naturally, be somewhat closer to the ground, than it would be, were the cannon-bone long and the pastern upright. Besides this, the appearance of a comparatively long cannon may, I venture to think, give the impression of greater length below the knee and hock, than would be the case, were the cannon short in comparison to the pastern. As regards the opinion that the length from hock to toe, as compared to that from hock to stifle—irrespective of the slope of the pastern—being less in some horses than in others, I must say that I think it is founded on an optical delusion. If we examine Fig. 313 we shall see a hock which certainly gives us the idea that it is "well let down"; but a look at Fig. 316 will convey to our minds the opposite kind of impression. And yet if we take a pair of dividers and describe a circle, with the point of the hock as a centre, and its distance from the toe as a radius, we shall find that in the case of both Fig. 313 and Fig. 316, the circumference will cut the curved fold of skin near the groin at the same point! For convenience' sake,
Fig. 316.—Sickle Hocks.

Fig. 317.—Thick-in below the Hock.

Fig. 318.—Fairly good "Bone" below the Hock.

Fig. 319.—Small "Bone" below the Hock.
I have taken these measurements, which are sufficiently accurate for the purpose in question; although it would have been more correct to have made them from the hock joint to the toe, and to the stifle joint, respectively. From whence arises, then, this difference of appearance between these two hind limbs, as regards the height of the hock off the ground? To this I would reply that the fact of the hock in Fig. 313 being "straight" (p. 210), gives the impression to the observer that it is better "let down" than the "bent" hock in Fig. 316; for, as the eye runs down the limb, it would not be so abruptly arrested by the former as by the latter kind of conformation. Also, the broader the bone is immediately below the hock (contrast Fig. 315 with Fig. 317), as compared to the width of the hind fetlock; the easier will the eye of the observer run down the hind leg.

**Cannon and Fetlock.**—Considering these parts, I have nothing to add to what I have already written in this chapter and in the preceding one, beyond saying that if the leg is of good width immediately below the hock, its shape will be all right down to the fetlock.

**Pastern and Hoof.**—As the hind limb is concerned more in propulsion than in resisting the evil effects of concussion; its pastern should be more upright, than what would be required in that of the fore leg. The hoof should more nearly approach the perpendicular, than the fore one; its slope, when viewed in profile, being, in unshod horses, about 60°. It is, as compared to its length, narrower; the ground surfaces of its quarters are straighter, and their respective curvatures differ less from each other, than those of the fore extremity. The horn at the toe is not so thick; the sole is more concave; the frog is narrower and less developed; and the heels are higher and closer together.
CHAPTER XX.

SKIN, HAIR, AND COLOUR.

Skin.—The chief functions of the horse's skin, as far as we are at present concerned, are: (1) to regulate the temperature of the body; (2) to aid in removing waste matters from the blood; and (3) to protect the body. As the first and second duties are intimately connected with each other, we may consider them conjointly.

The internal temperature being maintained by the changes which take place in the tissues; exercise, by promoting these changes, increases the production of heat. But as it also determines blood to the surface of the body, and thereby stimulates the sweat glands; the surplus heat is removed by an increased amount of evaporation from the skin, which performs this work, and also that of radiating heat, best when it is thin. Although the subject of health is outside the scope of this book, I may remark, in passing, that a soft and pliable condition of the skin is due to the fact of the oil glands, which are imbedded in it, being in good order. Granting the employment of clothing when necessary, we may assume that the skin of hard-worked horses, especially those which are engaged at fast paces, should, within reasonable limits, be as thin as possible, consistent with its being able to stand the friction and pressure of harness or saddle-gear.
**Colour.**—The colour of a horse's coat, as a rule, does not seem to be of much importance, as far as his useful qualities are concerned; although we cannot help being favourably impressed with those of rich and decided shades. Personally, I admire most a dark chestnut, or a dark brown with a tinge of rich claret-colour through it, as may be met with on rare occasions. Dark, bright bays are also very pleasing to the eye. Generally speaking, a horse looks best when his legs below the knees and hocks, mane and tail are darker than the rest of his coat. Bright chestnuts or bright bays, with white stockings and blaze, like many of the Blair Athol blood, form, perhaps, an exception to this, supposing, of course, that there is not too much white about the face. I cannot help sharing the general dislike to “mealy” chestnuts, and to bays and browns which are lighter on the insides of the limbs and on the lower part of the belly than on other portions of the body. The existence of this partial deficiency of colouring matter in the skin seems to infer want of nervous power; for we must remember that the distribution of pigment is greatly influenced by the nervous system. The common belief that if one fore leg is dark and the other white, the latter will be more apt to go wrong than the former, holds good, I think, only as far as the skin and hoof are concerned. Many persons consider black a “soft” colour, except, indeed, in the case of cart-horses, which are much admired when of that hue. The prejudice to which I have just alluded is, probably, due to the fact of many animals of this shade being “foreigners.” Grey is, undoubtedly, an unpopular colour. Apart from any feeling as regards the colour itself, it is true that it gets fainter as the horse grows older, and then unmistakably and perhaps unpleasantly proclaims the fact that the animal has passed his first youth. Besides this, a grey coat is difficult to keep clean, and is liable to contract stains which are hard to remove. The extra trouble thus entailed predisposes grooms to dislike grey horses, a fact which may account for the small number of grey horses in England, compared with those met with in
the East, where stable duties are not so onerous as in this country. I may mention that grey horses appear to be more liable to melanosis than animals of other colours. Shire horse fanciers do not like greys, for the majority of foreign buyers object to them. Some of their best horses, as What's Wanted and Rokeby Fuchsia, for instance, were of this hue. For my own part, I am very fond of dark iron or dappled grey with dark mane and tail. Among the cleverest hunters I have seen, I must say that a comparatively large proportion of them have been greys, a fact for which I can offer no explanation, unless that of their having had Chanticleer blood in their veins. In Leicestershire, moderate performers, as a rule, are averse from riding out hunting a grey horse, whose conspicuous colour is apt to draw attention to sins of commission and omission in too marked a manner to be always pleasant. Blue and red roans, and dun with black points, are supposed to be "hardy" colours. The most showy colours for harness work are bright chestnut and red roan with more chestnut than grey hairs, and free from white patches. When there is a large admixture of white with the red, the colour may be called strawberry roan, which is an ugly hue, particularly if the animal that wears it has a blaze and white stockings. Both piebald (black and white) and skewbald (bay or chestnut and white) may be suggestive of a circus, except in a team; although as clever a hunter (Fig. 320) as I have seen in Leicestershire was a skewbald. In a hunter, both piebald and skewbald are even more conspicuous than grey. The colours found among high-caste Arab horses are practically limited to bay, brown, chestnut, and grey. The same remark applies to our own thoroughbred stock, except that we have a few roans, and a very small proportion of greys chiefly through Chanticleer. The general idea that chestnuts are more impetuous than horses of other colours, is one which I do not think worthy of much weight.

Mr. T. C. Patteson, of Toronto, draws my attention to the very interesting fact that the offspring of two chestnuts
M. H. H.

Fig. 320.—Captain G. S. Williams's Hunter, Joseph. By the King; dam by Will Scarlett.

M. H. H.

Fig. 321.—Weight-carrying Hunter, the property of Prince Henry of Pless.
is always a chestnut (hence the uniformity of colour in Suffolk cart-horses), and that a grey is produced only when one or both of the parents are grey. There is a certain uniformity, which is by no means absolute, in breeding respectively from bays and browns, as we may see among Cleveland bays and brown Exmoors. Mr. Patteson informs me that two greys may produce a bay foal.

The colour of the skin itself is either black, pink (free from pigment), or it may be partly black and partly pink in patches. Although the large majority of grey and white horses have black skins; pink skin will invariably produce white hair, and will secrete (at the coronets) white hoofs. Black skin will form dark-coloured horn, even when the coat is white. Although, as I have just said, white horses may have black skins, we shall find that the skin of white markings (stars, blazes, reaches, snips, stockings, etc.) on dark-coloured horses is, as a rule, pink. In fact, I venture to say that the skin of white stockings is always pink, and consequently the hoofs of these legs will be white; provided, of course, that the white hair is continued down to the coronet. In the East we may not infrequently see pink-skinned horses, which, of course, are white, and which, according to my experience, are much "softer" in constitution than animals with dark skins. This fact is, I think, chiefly owing to the greater effect the rays of the sun have on skins which are free from pigment, than on dark-coloured skins. Besides, as human albinos are generally inferior, intellectually and physically, to their fellows, we may suppose that the same rule holds good with respect to these equine albinos. Experiments show that dark-coloured hair is capable of sustaining greater tension than blonde hair. Hence we have reason to assume that the protective cuticle and horn (both of which, like hair, consist of epithelium), secreted by dark-coloured skin, are stronger than those formed by pink skin.

English stable-men who make a practice of washing horses' feet, rightly consider that the animals under their charge
which have white pasterns, are more liable to get cracked heels than those which have dark ones. The supposed idiosyncrasy in this case is no doubt chiefly due to the extra amount of washing which the white pasterns receive, so as to give them a clean appearance.

**Colour in relation to Heat and Cold.**—Experience in tropical climates teaches us that the darker a horse's coat is, the better will he stand the effects of the sun. I may explain that dark surfaces radiate out heat and also absorb it faster than those of a lighter hue, as we may prove by the two following experiments. If we fill with boiling water two crockery teapots of the same form—one being white, the other black—we shall find that if they are both placed in a cool spot, the latter will lose its heat quicker than the former. If, however, they are filled with icy cold water, and are then exposed under similar conditions to the effect of the sun on a hot day, the black one will get warm in a shorter time than its fellow. We are also aware that the skin of natives of tropical climates is darker than that of inhabitants of temperate or cold countries; and that in the Arctic regions, the coats of various animals turn white on the approach of winter. The working of this natural law is most beneficent; for, as the temperature of the body of the polar bear, for instance, is much higher than that of the atmosphere in which he lives, he can lose nothing on account of his white coat being a bad absorber of heat; while the fact of its parting with (radiating) heat slowly, helps the body to maintain its normal degree of warmth. The skin of the negro, for example, although it absorbs heat quickly, radiates it still faster; for the vapour given off by the skin cools the surface, and also, by the mechanical protection it affords, tends to prevent the absorption of heat from the atmosphere. At first glance, we might, possibly, imagine that if the surrounding air was warmer than the internal temperature (about 99.5°F Fahrenheit for the horse), no cooling effect could be produced by radiation. When, however, the skin
HAIR ON THE LEGS OF CART-HORSES.

is ip healthy and untramelled action, its temperature, on account of the free evaporation of perspiration, is considerably under that of the deeper structures, even when the thermometer stands, say, 115° Fahrenheit in the shade. If, under such circumstances, clothing be worn, the garments will soon become almost, if not quite, as hot as the surrounding air, evaporation will be checked, except from the exposed parts, the temperature of the skin will rise, and the cooling process of radiation will be more or less stopped. In this case, any gain which may be obtained in lessening the absorption of heat, as persons do in hot countries, by wearing white will be a direct gain. During the summer months in tropical latitudes, the hair on a horse's body will, usually, be so short and thin, that its presence will offer no impediment to the action of the skin. Agreeably to the foregoing observations, we find that black and brown horses stand heat best; and that white—especially if they have pink skins—and grey animals sustain it comparatively badly. I have frequently observed on hot days in tropical climates that, other things being equal, grey horses sweated far more readily and profusely than those of darker shades.

Hair.—The possession of a fine glossy coat will naturally indicate that the skin is in active working order, and consequently in good condition for removing the surplus heat generated in the body by hard labour. The Desert Arabs, who have no objection to a thick mane, consider that unless a horse has a thin tail, he cannot be of high caste. The same idea seems to have given rise to the saying that one never sees a bad rat-tailed horse.

Hair on the Legs of Cart-horses.—It is a common belief that cart-horses with a good supply of hair on the legs have better bone than the cleaner limbed animals. Mr. G. M. Sexton, secretary to the English Cart-horse Society, in his essay on cart-horses, writes as follows: “One of the characteristics of the Shire horse is to have hair on the legs.
The hair should be long and thin, finer in quality on the mare than the stallion; it should grow from the fetlock above the knee, and the same behind the hock. By many this is thought to be a useless appendage, and that this abundance of hair is a cause of grease; but it is not so by any means. Hair is an indication of bone and size.” Mr. Frederick Street, in his *History of the Shire Horse*, gives “plenty of long silky hair on the legs” as one of the desirable points in the Shire horse. Mr. James Howard, M.P., in his *Notes on Cart-horses* (Royal Agricultural Journal, 1884), remarks that “A grave doubt, however, arises whether the profusion of hair and ‘feather’ insisted upon in show-yards and among the leading breeders of Shire horses is really so essential to strength and constitution as is generally asserted and believed. As a farmer of heavy clay land—much of it hilly—which requires very powerful horses in tillage and in carting, I have long entertained doubts as to the policy of the present tendency to such a profusion of hair. Breeders not only contend for hair on the rear of the legs, but many have also come to insist upon a mass of hair in front from the knee downward, doubtless a characteristic of many of the old Shire horses bred in Derbyshire early in the present century. Of course, no one contends that all this hairy covering is desirable in itself; it is advocated as being essential to hardiness of constitution and size of bone. This contention merely means that the desired constitution and sufficient bone have not hitherto been obtained without an abundance of hair.” This gentleman cites cases in which, for railway work, clean-legged horses are preferred to those with a plentiful supply of hair, on account of the latter being predisposed to grease and other forms of inflammation of the skin of these parts. We may readily see that legs which have a large amount of coarse hair on them would be predisposed to grease and other allied ailments; for, as both hair and scurf skin are secreted by the true skin, we may infer that if the former is thick and coarse, the latter will be strong and harsh, and conse-
quently, the oil which is secreted to keep the surface soft and supple, will not be able to perform its duty as efficiently as it would do, were the scurf skin thin. When the scurf skin gets hard and cracks from the effects of climate and from its being insufficiently supplied by this oil, the highly sensitive true skin becomes inflamed from irritation due to exposure. The fact of cart-horses being peculiarly liable to "sallenders," if they are blistered for "bog spavins," taken in connection with the coarseness of their hair, as compared to that of lighter breeds, would seem to support the opinion that the coarser the hair, the more liable is the animal to suffer from inflammation of the skin, of which grease is a form that is very difficult to entirely allay. We may safely conclude that if hair on the legs be desired, it should be soft and silky in its nature. I may mention that Prince William, who, as a two-year-old, was the champion of all classes in the Shire Horse Society's show for 1885, had the best hair I have ever seen on a cart-horse. Mr. Thomas Dykes, in his essay on *The Clydesdale Horse*, states that "the back part from the knee down should possess a nice flowing fringe of silken hair, which should spring from the very edge of the bone. This hair should be of what a judge of a Skye terrier would style a 'pily' nature; and good judges will not have a horse at all, the feather of which has a coarse matted appearance. The high value set upon nice silky hair is on account of its being an indication of strong, healthy bone, and as hair of a short coarse matted kind suggests a tendency to grease."

Mr. John Anthony, the well-known Norfolk breeder of hackneys, tells me that Shire horses, bred on chalky soil, like that in Norfolk, never have as good a show of hair on their legs, as those brought up on land with less lime in it.

**Markings.**—When a dark-coloured horse has a small patch of white, more or less in the centre of his forehead, it is called a "star" (Fig. 237). If the white spreads over the forehead, it is termed a "blaze" (Fig. 232). If it runs
down the nose in the form of a line of no great width, it is known as a "reach" or "stripe" (Fig. 249). A white or pink patch on either lip is called a "snip" (Fig. 249). White, reaching down to the coronet, on the leg of a dark-coloured horse, is, as we all know, termed a "white stocking" (Fig. 269), an expression that might be reserved for one that comes up as high as the knee or hock, while that of a "white sock" (Fig. 268) might be used to signify the marking when it is shorter.
CHAPTER XXI.

ACTION, HANDINESS AND CLEVERNESS.

Action.—General Remarks on Action.—The three chief requisites of action, from a useful point of view, are: sure-footedness, effectiveness, and lightness, so that the limbs may not unduly suffer from the effects of concussion. As remarked many years ago by Dr. Carson, the safety of a horse’s action depends on the way he puts his feet down, rather than on the manner in which he picks them up. We should, therefore, from this point of view, attach no value to high action, beyond what is sufficient to enable the animal to avoid striking his toes against any inequalities which may be on the surface over which he is going. The stability of the fore limb, when the foot comes on the ground, depends, to a great extent, on the knee being kept straight, which is mechanically done, without the expenditure of muscular force, if a line, drawn from the heel to the centre of the elbow joint, falls at that moment in front of the centre of the knee joint. The more upright the pastern, the further will this line be drawn back as regards the position of the knee. As the shoulder blade and pastern are at opposite ends of the column of bones of the fore limb, and as they both slope in the same direction, it follows that the degree of slope of the shoulder will influence that of the pastern. Hence, for safe action, we should seek for oblique shoulders, sloping and long pasterns, knees in which there is no tendency to “stand over,” and lightness of fore hand.

For effectiveness, the action should be the happy medium between a cramped style of going, and one in which
command over the limbs is, to a certain extent, lost by the stride being too long.

By the term lightness of action, I wish to specify well-balanced movements of the limbs, by which undue weight is thrown on none of them, and particularly not on the fore hand. The action, from a "level" point of view, is influenced by the conformation of the body, and by the carriage of the head and neck. To be perfect at fast paces, we require the animal to be light in front, to have oblique shoulders and sloping pasterns, so as to have full power to raise the fore hand; and to have good loin muscles. On page 67, et seq., I have treated of the carriage of the head and neck. In heavy draught we do not require lightness of action, which is the direct opposite of throwing weight into the collar.

The Walk—At this pace, like at all others, the shoulders should work with the utmost freedom, and the fore foot should be thrown well to the front and only high enough to clear and cover the ground. We may see this beautiful play of the shoulders to perfection in young thoroughbreds. The hind legs should be swung freely to the front, so that they will considerably overstride the imprints made by the fore feet. Viewed from behind, as well as from the front, the near and off pairs of legs should respectively move in the same line, so that there may be no "dishing" or crossing of the legs. The hocks should have no in-and-out movement, as may be sometimes seen, and had better work rather close together than wide. Any tendency to stumble or knuckle over behind is a serious fault, unless it be solely due to bad shoeing. If the horse be given a long rein, he should carry his head rather low and well advanced, and should be able to walk at the rate of about five miles an hour.

The Trot.—At the fast trot, the fore leg should be brought to the front with a straight knee, the foot appearing as if suspended for a brief moment (Fig. 208) before being placed down. The knee should not be raised higher than what would be sufficient to make the fore arm horizontal, or not quite so much. The hind legs should be carried
well forward, and should work in perfect unison with the fore limbs (Fig. 405). Nothing looks worse than to see a horse trotting high in front, and dragging his hind legs along the ground. As I have already remarked, with reference to the walk, there should be no “dishing” or crossing of the legs, so that, when viewed from behind, a clear space will be preserved between the near pair and the off pair of legs. I may explain that a horse “dishes” with a fore leg when he throws the foot outwards as he raises it off the ground. In the trot, the head should be carried much higher than in the walk; as the limb has to be raised to a greater extent. Fig. 207 shows the “extravagant” action which is greatly prized among fashionable harness horses.

*The Gallop.*—In order that the animal may utilise to the utmost his forward reach in the gallop, the knee of the leading fore leg should be kept as straight as possible while that leg is being extended to the front. In fact, the straighter it is at that moment, the more perfect will be the front action on level ground. A race-horse should, like a ballet dancer, move as if he had no knees. I may, however, qualify my praise of low action by remarking that a horse who bends his knees a little, is better suited for going up a hill, than a “daisy cutter”; as his “round” style of going will aid him in climbing the ascent. Heavy shoes on the feet have a marked influence in making horses go “high” in all their paces, a fact which has been largely utilised by American trainers in regulating the action of their trotters. As this tendency is detrimental to the speed of race-horses, their shoes should be as light as practicable. In India, where but very little rain falls during the racing season, I have trained and run many of the horses I have had in my stable, without shoes of any kind. I have mentioned, on p. 69, that curb bits are objectionable for use with race-horses, on account of their tendency to make horses gallop “round,” or to “fight” in their action. In the former case, the animal will carry his head low and bring his chin into his chest, with
the object of transferring the pressure, as much as possible, to his poll, over which the head-piece of his bridle passes, and will consequently bend his knees too much. In the latter case, the animal will keep his head stuck up in the air, probably, in the vain attempt to get his jaw away from the painful contact of the curb chain.

If we observe a "true" galloper, we may note that he holds his head and neck in a more or less uniform position (pp. 70 and 71), so as to enable the muscles of the neck to work in a regular manner.

The hind legs, at the gallop, should be brought well forward under the body, with particularly quick recovery after having been straightened out. Their action, like that of the fore hand, should be characterised by the machine-like regularity of their forward and backward sweep. The limbs should move in such perfect accord one with the other, that there should be the least possible rise and fall of the fore hand; for if the weight be depressed at one moment, it will have to be raised during the next, by an expenditure of force which will be wasted as far as progression is concerned.

Leaping.—In Chapter XIII. we have seen that the "take-off" in the leap consists in the raising of the fore hand and in the propulsion of the body. Hence, at that moment, the animal should have his head raised and somewhat drawn back, so as to "lighten" the fore hand, for which object, and in order to be able to fully bend the hind legs, he should have them well under him (Fig. 195). To obtain the maximum effect of propulsion, the horse should straighten his hind legs to their utmost extent (Fig. 200); and to clear the object, if it be one that is likely to tax his powers to "negotiate," he should raise his knees well and should bend them as much as he can (Fig. 196). The instant the hind feet quit the ground, they should be drawn up as quickly as possible and close to the body, so that, in high jumping, they may not catch in the fence, but be ready to save the animal from a fall in the event of an accident, and to enable him to land in safety. On clearing the obstacle, the fore feet should be
brought well to the front, and as they respectively come to the ground, their knees should be quite straight (Figs. 199, 206 and 409). The head should be somewhat raised and the muzzle drawn in a little, so as to bring the weight back, and to enable the horse to see where he is going to place his feet.

**Handiness and Cleverness.**—The "handiness" or "cleverness" of a horse depends on his conformation, disposition, and training, with which we are not at present concerned. It goes almost without saying, that a placid-tempered animal would be easier to stop or turn than an excitable one, and would be consequently handier; but I cannot say that he would be cleverer. I have known several terribly hard-pulling steeplechasers that were as "clever as cats," and always had a "spare leg" for every difficulty, provided their rider did not interfere with their mouth, and I have seen other equally stiff-necked, cross-country horses, whose sole delight, no matter how lightly they were handled, seemed to be punching a hole in every fence they met. Some temperate ones are just as "chancy," apparently, from pure laziness; though many quiet animals are incapable of making a mistake.

The points of conformation which conduce to handiness and cleverness are:

1. Well set on head and neck, so that the horse may be able to bend readily to the rein.
2. Light in front (head, neck, and shoulders), and having well-sloped shoulders and oblique fore pasterns, in order that the animal may be able to raise his fore hand with ease, and bring his weight back.
3. Strong loins. We must remember that the upper loin muscles are "rearing muscles" (page 52), and that the lower ones assist to bring the hind legs under the horse.
4. Strong hocks.
CHAPTER XXII.

CONDITION, AND GOOD LOOKS.

Condition.—I use this term here to signify the bodily state in which a horse can, in the best possible manner, do work that will test the power of his lungs and muscles to the utmost. I shall make no reference to "dealers' condition," which is a subject that does not come within the scope of conformation.

A horse to be in condition should be healthy and sound; should have his breathing apparatus in the best possible working order; his muscles developed to the highest degree of perfection, with regard to the nature of the task they have got to perform; and the amount of fat in his system should be reduced to a minimum consistent with health.

I shall now glance at the chief signs of condition in the horse.

1. Health and Soundness.—The latter, apart from the former, need not be considered here; for it belongs to the domain of veterinary science. The ordinary indications of health are: coat, bright; skin, cool (except when heated by exercise, or by the sun), soft and loose over the muscles; eyes, bright and soft in expression; visible mucous membranes of the eyes and nostrils, healthy looking; mouth, sweet smelling; internal temperature (in health about 99.5° F.); pulse (from about 35 per minute for heavy cart-horses, to about 45 for small ponies); and rate of breathing (10 to 12 per minute, when at rest), normal. The dung should be fairly well formed, free from mucus, and from any offensive smell.
DEVELOPMENT AND LEANNESS OF MUSCLES.

The appetite as a rule should be good; although horses may become a bit "dainty" in their feeding, when they have been wound up in their training to "full concert pitch."

2. Development and Leanness of Muscles.—The muscles of the croup (those over the quarters) should present a rounded surface, and those over the loins and back, at each side of the backbone, should stand out in bold relief. The line (sometimes known as the "water-mark") down the thigh (Fig. 260) should be clearly apparent. The muscles just above the fore arm should form a rounded mass, and those of the shoulders should be well defined. There should be over the ribs a thick sheet of muscle, which should show well above the level of the part of the flank in rear of it. This muscular covering of the ribs terminates abruptly in an irregular line which goes downwards and backwards in the direction of the groin, and which can be seen plainly only when there is no excess of fat about the part. I may explain that in forced respiration (p. 39), the muscles which cover the ribs are brought into active play, and they consequently become largely developed by the process that brings the galloper, or fast trotter, into condition. Hence, if there be in a horse a marked difference of level between the surface in front of the line in question, and that in the rear of it (Fig. 322), we may reasonably conclude that he has done a good deal of that kind of work which brings his lungs into rapid action, and that his system is not overloaded with fat. The fact of the "water-mark” being clearly indicated is also dependent on the absence of fat about the part.

The line which marks the termination of the sheet of muscle to which I have alluded, corresponds to the posterior border of the fleshy portion of the panniculus, and indicates the commencement of the aponeurotic portion. The "water-mark,” or "quarter-mark,” to which I have also drawn attention, is the line of separation between the rotator tibialis and the abductor femoris.

The most time-honoured method of ascertaining whether or not a horse is in condition is to feel his crest with the hand, so as to find out if it be hard or soft. This plan has its merits; for the crest is a part on which many "heavy-necked" horses
(Fig. 263), especially entires, have a tendency to deposit fat. I need hardly say that a thick layer of fat would feel softer to the touch than a mass of ligament, muscle and tendon; and that the nearer a horse approaches the cart-horse type, the heavier is his neck.

The diagonal line on the flank, the appearance of the ribs through a thick layer of muscle, and the lean though muscular condition of the shoulders of a race-horse in training, are well shown in the photograph of Ormonde (Frontispiece).

3. Signs of condition afforded by the state of the breathing. — Although a practical trial would give an experienced observer the best possible idea of the state of an animal's organs of breathing; the question depends so much on individual merits and defects, that it is very difficult to lay down any fixed rules for guidance in making such a test. Supposing that the horse had done his work in what we considered a satisfactory style, we might prove the correctness of our judgment, by observing the manner in which he would recover from the effects of his exertion. If after a sharp "rough-up," his lungs resumed a tranquil form of breathing, when he had rested or (better still) had been walked about for a few minutes, and if he did not show any appearance of being distressed by the severity of the work, we might fairly conclude that his "pipes" were in good order. Trainers generally think that the fact of a horse "blowing his nose" (as a kind of sneeze which these animals sometimes make after a quick "spin," is called) is a sign of the wind being all right. I may also point out that if the wind of a hunter is not "clear," he will be unable to quickly "come again," if he gets out of breath during a run, even if he be "eased off" for a little with the object of letting him "catch his second wind." If a strong gallop has the effect of making a horse unusually thirsty, we may doubt that his lungs are in good order. To find out, in doubtful cases, whether or not a horse is a roarer, we had best, immediately
after the animal has done some fast or severe work, apply the ear close to one of his nostrils.

Large calibre and thinness of the walls of the nostrils, which condition predisposes a horse to "high blowing," is a sign that the animal's organs of breathing are naturally good.

4. Signs of condition manifested by the state of the sweat.—The fatter a horse is, the thicker and more greasy will be his sweat. When a horse is in condition, his sweat will come off like water, will have lost the saline taste it previously had, and, unless the animal is in a state of excitement, it will dry on the skin with extreme quickness, as soon as the work which had opened the pores has been stopped. If a horse which has no excess of fat in his system, shows a tendency to sweat on a very slight provocation of work or "closeness" of atmosphere, and if the perspiration thus induced, takes a long time to dry on the surface of the body, we may reasonably conclude that general weakness is the cause of this excessive action of the skin. I may explain that when a horse sweats from excitement (as on a race-course), the surface of the body thus moistened will not dry quickly; for as long as the excitement lasts, the outpouring of the fluid will more or less continue.

**Good Looks.**—Beauty in the horse is dependent:

1. On the uniformity of type which the various parts of the body bear to each other. Thus, a Shire or Clydesdale horse, with his Roman nose, loaded shoulders, and short legs, may be quite as handsome as a good-looking English thoroughbred, or a showy, high-caste Arab.

2. On the artistic arrangement of the lines of his body. We may see the importance of this from a beauty point of view, if, for example, we contrast a photograph of a horse having the ears pricked forward, with another one of the same animal, taken a moment afterwards, but having the ears in a normal position. The former may look handsome, and the latter plain; although the two may be absolutely
CONDITION, AND GOOD LOOKS.

identical in every particular, except in that of the ears. The "line of beauty" (alternate convexity and concavity, or vice versa) is well exemplified from the tip of the off ear to the top of the croup, in Fig. 371; in which there is, however, a too sudden depression of the quarter. The outlines of the tail are very graceful in Fig. 370. The curves from tip of ear to end of tail are also good in Fig. 236, except that the line of the crest might be slightly more convex. For beautiful curves of the upper line of the body, from tip of nose to tail, see Figs. 234, 324, 327, 328, 334, 346, and 356. One reason (which possibly might escape the notice of a casual observer) why the pictures or photographs of some horses (Figs. 270, 322, and 370) look well, is that the curves of the under part of the body—from muzzle, lower lip, along lower jaw, under throat, down neck, in front of chest, along the belly, under groin, and carried in front of both hind legs—are very graceful. In all cases, oblique shoulders, sloping pasterns, long and well-arched back ribs, muscular loins, more or less horizontal pelvis, tail set high up, straight-dropped hind leg, will be beauties.

As heavy cart-horses are often somewhat “back at the knees” (p. 194), the presence of a good supply of fine hair behind the back tendons, increasing in amount from the knee to the fetlock, will balance this concavity. I do not think that docking, except when it is done to remove an unsightly “kink,” ever improves the appearance of a horse, from an artistic point of view. The removal of the forelock, when hogging the mane, is always an eyesore. Whenever good looks are sought to be studied, the mane should not be haggled, if the animal has a light neck. As a horse is looked at more frequently from the near than from the off-side; his mane, as a rule, should fall to the off-side.

Under this heading we must also put good carriage of the head and tail, and true and showy action. For carriage of the head and neck, see p. 67, et seq. The tail during movement should be held well out, with the hairs falling from it in graceful curves. To look well, the limbs should work in
lines parallel to the direction in which the horse is going; for any crossing or dishing of the legs will detract from the grace of their movement. Somewhat lofty, "cadenced" action in the walk or trot of the hack or charger will be pleasing to the eye, as it will suggest the possession of force and speed held well in reserve.

I need hardly say that a bright, intelligent expression of face, which is greatly assisted by the movements of the ears, adds much to the beauty of the horse.

As regards colour, see Chapter XX.
CHAPTER XXIII.

WEIGHT-CARRYING AND STAYING POWER.

Weight-carrying Power.—The special points for weight-carrying power are:—

1. Length and obliquity of shoulder-blade (p. 182 et seq.).

One might be inclined to think that very oblique shoulders are not an advantage from a weight-carrying point of view; for they necessitate the saddle being put farther back on the horse, than would be the case with shoulders of only a moderate slope. At the same time, we must remember that with horses of the same depth of body at the withers, the more oblique the shoulder-blades, the longer they will be.

2. Strong loin muscles.

3. Good substance and fine quality of bone.

Ormonde (Frontispiece), "the horse of the century," St. Gatien, the dead-heater for the Derby and winner of the Cesarewitch, and Cloister (Frontispiece), were horses of great bone, and marvellous weight-carriers.

4. Pasterns not too sloping.

5. Absence of undue weight of body beyond that which would be necessary for the movements of the limbs, and for the performance of the various vital functions.

The foregoing rules would apply to all classes of horses. For absolute weight-carrying power, the animal should have short legs (a fact which would be incompatible with the possession of speed), and should have his pelvis somewhat drooping.
Staying Power.—The ability to “stay a distance,” granting the possession of health and condition, depends
(1) on the breathing power being good; (2) on the muscles working to advantage, and on the conformation being of the
required kind; and (3) on the action.

With respect to the first condition, we require the barrel to be deep and rounded behind the girths (p. 163), and the flanks to be well ribbed-up.

The second condition will be best fulfilled, from the point of view of speed, when the muscles over the loins are powerful, and when the fore hand is light; that is to say, when the shoulders and pasterns are oblique, and the head, neck and shoulders light, in which case the fore legs will not be wide apart (p. 169). As thick muscles are unsuited to bear the strain of continued quick work, we usually find that genuine stayers at fast paces are not heavily built horses.

Any excess of height over the croup, as compared to that at the withers, will add to the weight on the fore hand (p. 40). The fact of the neck (p. 154) being abnormally short in comparison to the limbs, will naturally detract from the staying power. The same remark applies to the possession of “sickle-hocks” (p. 51). In heavy draught, the mechanical advantage will be on the side of a heavy fore hand.

There is an important difference between staying power (using the term in its racing sense), and ability to endure fatigue. For instance, East Indian ponies, though often very fast for a short distance, are notoriously bad stayers; and yet they are wonderfully good animals on a long journey. Thus, many of them which are incapable of “getting” beyond three furlongs in a race would, if harnessed to an ecka (a native two-wheeled trap), do, comfortably, 70 or 80 miles from sunrise to sunset, with the thermometer at noon up to 110° F. or more, in the shade. Here the lack of staying power would be due to the organs of breathing being unable to continue work under high pressure. As might be expected, these “country-bred” ponies (Fig. 377) are, as a
rule, light behind the girth, flat-sided, and badly ribbed-up. With thin necks and light shoulders, their good legs and feet have but little weight to carry; and as the quality of their tissues is of the best, and their spirit undeniable, they can go marvellously long distances without getting knocked up—provided always that they are not over-paced or over-weighted. I need hardly say that a genuine stayer will also be capable of appearing to advantage in a "go-as-you-please" task, for he will possess all the good points of the other, with better organs of breathing. The small amount of extra weight (on account of increased length of rib) which he will have to carry, will be more than compensated by the larger space allowed for his digestive organs. As a rule, in proportion to their respective sizes, small horses will stay better, and will be capable of enduring more fatigue, than big horses. The reason for this appears to be that the former have more vitality than the latter, on account of the rate of the circulation of their blood being quicker.

I need not point out the advantages of good action in the present connection.
CHAPTER XXIV.

BLOOD, SYMMETRY AND COMPENSATIONS.

**Blood.**—The relation of "blood" to conformation is its only one which need be considered here.

The term "blood" usually signifies more or less pure descent from animals mentioned in the English Stud Book, or from high-caste Arabs. In our Colonies, the initials T. B have a more elastic application than in the Mother-country. As English thoroughbred horses have been bred almost entirely with the object of their utilisation on the Turf; their conformation more or less resembles that of the galloper. Were I to be asked to particularise the "point" or "points" most characteristic of the English "blood" horse, I would answer: "The legs below the knees and hocks." Their special peculiarities, in this respect, are: lightness of bone, thinness of skin, fineness and shortness of hair, small amount of underlying connective tissue, near approach to parallelism of back tendons to cannon-bones, with consequent smallness of fetlock joints (p. 194), good length of pasterns, and small hoofs with well-arched soles. These hard-looking, though light-shaped legs, are evidently the production of a dry, warm climate, during many generations in the East; for although we rarely, if ever, see them in pure Western stock, we may find them in profusion among Arab, Barb, Persian, East Indian, and South African horses, all of which have been bred in a hot, dry climate. The speed of the thoroughbred is the result of careful selection in breeding, by which, not only has the best form of conformation been obtained, but also the most suitable kind of nervous organisation. The effect of
heredity is specially shown in the working of the nerves, which regulate the exhibition of all muscular force. Although they can in no way increase the actual strength of a muscle, its failure or success in putting forth its full power, and also its speed of contraction, are dependent on them. Hence, two horses of identically the same “make and shape” (if such a thing were possible) might differ widely in pulling power, handiness, or speed, on account of a want of similarity in their nervous systems. We see this fact well marked among men, in whom uncommon quickness and great dexterity of muscular movement is often inherited. The speed thus obtained from “blood” independently of conformation, may be regarded as an outcome of heredity. In judging, therefore, by a horse’s conformation, of his suitability to any particular kind of work, we should take into careful consideration all the “blood” points which he may possess. The fact of a horse having Arab blood in his veins, is, in itself, no reason for our inferring that he has a good “turn of speed”; for Arabs, though charming hacks and admirable light cavalry troopers, are not race-horses.

It is noteworthy that thoroughbred stock which are allowed (as they often are in the Colonies) to run wild, say, up to four or five years old, before they are taken up, and which are then put to ordinary labour, lose in a great measure the blood-like appearance they might have possessed, had they been handled early and put into training in the usual way.

Symmetry is the conformance, as regards size, shape and arrangement, of the various parts of the body to some particular type of useful horse.

In violation of this condition, we may have united in the same animal the long legs and light body of the racehorse, and the heavy head, loaded neck and thick shoulders of the cart-horse; or the contours of the race-horse, with the exception of the loins being weak, and the hind legs short with drooping croup. Even with the ordinary saddle-nag, to say nothing of the hunter and officer’s charger, we have
Too often the massive shoulders of the draught-horse. A heavy head, which reveals but too plainly a cart-strain, is a terrible eyesore to an animal whose neck and shoulders are light, and which might otherwise be a high-class hack.

We may see short-legged, deep-bodied cart-horses, with great power of limbs and shoulders, having weak loins. A horse which has oblique shoulders should also have sloping pasterns and a horizontal croup. We must here allow for the fact that "work" often renders the pasterns abnormally upright. We may witness many instances of want of symmetry in the "tying-in" of the legs under the knees, short pasterns, and large, flat feet of long and slender-limbed horses. Fig. 284 shows a mare that was of fine width just below the hock (p. 211), but was tied-in below the knee. A mean carriage of the tail will contrast very unfavourably with a showy and graceful bearing of the head and neck.

The generic term "weed" is applied, usually, to long-legged animals which are weak in the loins, and are light in the back ribs. As a rule, the cause of their comparative worthlessness is wrongly attributed to the length of their limbs, rather than to their defects of loin and rib. If we compare Fig. 268 with the Frontispiece, we shall see that the mare in the former was actually "longer" and "lower" (taking the proportion between her height at the withers and her length of body) than the deep-ribbed and strongly "coupled" Ormonde. It is evident that no amount of shortening of her legs could improve her conformation.

Compensations.—The points which I shall consider under this heading have special reference to the saddle-horse and light trapper:—

"Plainness" of head will be best "carried off" by a "kind," intelligent expression of face; quick play of the ears, which appear to most advantage when they are small; good carriage of the head; and graceful setting-on of the head with the neck. The size of the latter should conform to that of the former.
Undue lightness of neck.—Full mane; light head, small ears, sloping and flat shoulders.

Heavy neck and loaded shoulders may be corrected to some extent, from a beauty point of view, by a good-looking, intelligent head, nice crest, and light mane. From considerations of utility, we should have the shoulders and pasterns sloping; the bones, muscles, tendons, and ligaments of the fore limb below the shoulder strong; feet good; and loins and hind-quarters powerful. For cross-country work strong; sloping fore pasterns are the best compensation for shoulders that are upright and heavy.

Fore legs below the elbows too light; Pasterns too upright, or too oblique.—Legs otherwise well-shaped; light fore hand; sloping shoulders; and good loins.

"Calf knees," or "over at the knees."—Strength of leg below the elbow; parallelism of back tendons with cannon-bones (p. 194); sloping shoulders; light fore hand; strong loins.

Ribs "flat-sided."—Good depth of body at lowest point of back; flanks well ribbed-up.

Too hollow in the back.—Light fore hand, sloping shoulders, and in all cases, broad, powerful loins, which is the special kind of compensation in this instance.

Loins too light, and flanks badly ribbed-up.—Light fore hand; shoulders and pasterns oblique; light abdomen; well-rounded barrel; strong hind-quarters; good gaskins; "straight-dropped" hind legs.

Hind-quarters too light.—Light fore hand; shoulders and pasterns oblique; light, but well-rounded barrel; muscular loins; good gaskins; "straight-dropped" hind legs.

"Sickle hocks."—With this defect in a saddle-horse which would be required for fast work, it would be well for him to have good length of hind legs, the possession of which will presuppose that of a horizontal pelvis; and the compensations mentioned in the preceding paragraph, with the exception of "straight-dropped" hind legs, which is the opposite kind of conformation to that which we are considering.
CHAPTER XXV.

SPECIAL POINTS OF VARIOUS CLASSES OF HORSES.

The Race-horse—The Racing Pony—The Hunter and Steeplechaser—The Heavy Cart-horse—The Harness-horse—The Hack—The Lady's Horse—The Cavalry Trooper—The Officer's Charger—The Artillery Horse—The Light Vanner—The Polo Pony.

The Race-horse.—1. The height of the galloper at the withers, and also over the croup, should be at least equal to his length of body (p. 127, et seq.).
2. The depth of the body at the withers should be considerably less than half the height (p. 128).
3. The loins behind the cantle of the saddle should be flat on account of the presence of largely developed muscles (pp. 52 and 172, et seq.).
4. The gaskins should be broad (p. 209).
5. The neck should be long (p. 154).
6. The fore hand should be light (p. 185). Consequently, the neck should be free from "lumber"; there should be but little width between the fore legs (p. 168, et seq.); the shoulders flat and without any "place for the collar" (p. 185); and the horse should not be thick between the upper ends of the shoulder-blades (p. 184).
7. The withers should be high, and should run far back.
8. The hind legs should be long.
9. The hocks should possess the ability of being freely straightened out, as well as bent.

As types of English race-horses, I may instance the following:—

Ormonde (Frontispiece), by Bend Or out of Lily Agnes, was, I need hardly say, the race-horse of the century. In
training, he was a little higher at the withers than long in the body; and about as high at the croup as at the withers. His legs, though long, were muscular, and their bones strong, as we may perceive from the appearance of his fore arm and gaskin and from the shape of the limbs below the knees and hocks. He had a particularly straight-dropped hind leg. Although he was in training when this photograph was taken, he shows great depth of body in the centre of the back: a fact which points to the unusual length of his back ribs, and to the admirable shape of his chest for purposes of breathing. I may point out that his roaring infirmity, being a nervous disease of his larynx, had nothing to say to his conformation. As his neck agrees in length with his limbs, and as his withers run far back, he had a very long "rein." His neck, though muscular, was light for a four-year-old entire. He was coarse about the throat, where the head and neck join. The horizontal marks on his legs, on and near his fetlocks, were curls in the hair, due to bandaging. His back view (Fig. 289) shows that he was narrow behind as compared with a middle-weight hunter (Fig. 288). His hocks were particularly good. His tail was placed very high on his croup.

Fig. 9 shows St. Simon (by Galopin out of St. Angela) slightly fore-shortened. Fig. 229 gives him in strict profile; but as it had to be copied from a photograph which was not good enough to bear reproduction, its details have not come out as well as I would have wished. They were both done in 1884, when St. Simon was a three-year-old, and when he was in training. Owing to the death of his first owner, Prince Batthyany, his nominations for the great three-year-old events were rendered void. Despite the fact that he had never met a great race-horse, he won all his contests with such consummate ease that I am inclined to think that as a two-year-old towards the "back end" of the season (1883) and for the first half of his three-year-old career—in other words, as long as he kept sound—he was as fast a horse, with, perhaps, the exception of Ormonde, as ever lived. St. Simon's height at the withers, or over the croup, is considerably more than his
Fig. 322.—H.R.H. THE PRINCE OF WALES' PERSIMMON.

Clarence Hailey.

Fig. 323.—H.R.H. THE PRINCE OF WALES' FLOREZEL II.
length of body. Also, his back and loins are remarkably short, and his shoulders are long and extremely oblique. I remember having been greatly struck by the marvellous beauty of his shoulders, and by the shortness of his back and loins, when I saw him for the first time, when he was sold as a two-year-old in 1883, after the death of his owner. Both his fore hand and hind-quarters were light. He was extremely round in the back ribs (p. 163), and was very well ribbed up.

The possession, in the same year, by H.R.H. the Prince of Wales, of two such good horses as Persimmon (Fig. 322) and Florizel II. (Fig 323), is a matter of congratulation to every lover of racing. The winner of the Derby and St. Leger, having been photographed a couple of days after he had won at Epsom, looks somewhat light, though muscular and very fit. His straight-dropped hind leg, powerful gaskins and hocks, light fore hand, and beautifully shaped fore leg from elbow to hoof, proclaim his “quality.” Time will no doubt make him deeper in the back ribs. Florizel II. is also a race-horse all over.

In 1871 Hannah (Fig. 325) won the Oaks and St. Leger, and Favonius (Fig. 324) the Derby of the same year. They were in the same stable as Corisande, who won the Cesarewitch of that season carrying 7st. 12lbs. Lord Suffolk states, in the Badminton book on Racing, that Favonius was 16 or 18 lbs. better than either of the two mares, but that he became unsound. Accepting this estimation, we must regard him as one of the best horses of the century. We might have inferred the fact of his superiority over Hannah by noting that he was much deeper in the body behind the saddle than she was, and consequently his chest was better formed for forced breathing than was hers. He looks up to more weight than she does, on account of his fore arms and gaskins being more muscular, and his bones below the knee being larger. Both animals have equally “straight-dropped” hind legs. Her neck is lighter, and her shoulders appear flatter and more oblique than his. Both have almost exactly the same proportions.
between the length of body and the height at the withers, and between the depth from withers to brisket, and the height of the brisket off the ground. As both were in training, and standing in nearly the same position, we have a good opportunity of comparing their respective conformation.

Cremorne (Fig. 326), by Parmesan out of Rigolboche, won the Derby of 1872 against a bad field, with the exception of the roaring Princei Charlie. His produce have been famous for their jumping powers. He is standing so awkwardly in his photograph that it is difficult to form from it a correct idea of his "make and shape." He seems to have had a long shoulder-blade and a light neck, both of which are important jumping points.

La Flèche (Fig. 230) shows two essential points of speed, in being long on the leg and having but little to carry. By comparing Fig 230 with Fig. 229 we shall see that La Flèche is longer in the body and not so closely "coupled" as St Simon.

The Racing Pony should possess all the points of the race-horse which have been described under the preceding heading, but modified where necessary, by conditions suitable to superior ability for carrying weight; for racing ponies, in comparison to their height, have almost always to bear much heavier burdens than race-horses.

I cannot give a better illustration of a 14-hand thoroughbred racing pony of the highest class than that of Predominant (Fig. 236). He was sent from England to India, where he easily beat everything of his size in that great home of pony-racing. Mike (Fig. 235) was in a high state of excitement when he was photographed, as we may see by his stiffened tail, erect head, pricked ears, and by the collected manner in which he was standing. He had capital shoulders, good legs, and, like St. Simon, had not much to carry. He was one of the best 13.1 ponies ever bred in England. Water Lily (Fig. 332) was a very good 13.2 pony. For remarks on Arab racing ponies see p. 265, et seq.
Frank Haes.

Frank Haes.

Fig. 325.—Baron Rothschild's Hannah.

To face p. 244.
The Hunter and Steeplechaser.—1. The fore hand should be light. This point is of special importance in the Leicestershire hunter, the goodness of whose shoulders is probably more severely tested by the ridge and furrow than by the jumping, which is particularly trying, owing to the fact that the animal must "spread" himself out and go fast. Many hunters which would be of no use in Leicestershire, on account of having heavy shoulders, perform brilliantly in Ireland, where jumping on and off banks, and galloping on a smooth surface do not "find out" their weak point.

2. It is a defect in the cross-country horse to be higher at the croup than at the withers, or even to be the same height at these parts (pp. 130 and 40); for he requires to be light in front, and to have the bones of his fore limbs comparatively long, so as to be able to efficiently raise his fore hand, both when taking off and landing.

3. The shoulder-blades and pasterns should be long and sloping.

4. The muscles which lie along the front portion of the shoulder-blade, and the lump of muscle above the fore arm should be well-developed (Fig. 329); as the former straighten the shoulder joint, and the latter straighten the elbow joint; two actions which help to prevent the horse from falling when he lands over a jump.

5. The muscles over the loins, behind the saddle, should be particularly strong (p. 52).

6. The hocks should be large; and their straightening power (the gaskins) broad.

On page 208, I have alluded to the favour which hunting men in Ireland accord to goose-rumped hunters, and which is fully justified in practice.

A high-class Leicestershire hunter is undoubtedly the best type of horse in the world; for he unites in himself the greatest number of useful qualities: speed, strength, staying power, cleverness, courage, good manners and mouth. The speed possessed by that fine steeplechaser, The Doctor, made him all the better hunter in The Shires. We may
be quite certain that no horse is too fast for a Leicestershire pack of hounds which gets well away with a clear start from the field, behind a stout and straight-running fox, and with a good scent. The two horses which, to my thinking, more nearly approached in conformation the ideal Leicestershire hunter than any others I have ever seen, were Cloister (Frontispiece), the greatest chaser of all time, and Liberator, who was unapproachable in his day. Both of them were well able to carry 15 stone to hounds, which is a task that should not be beyond the compass of the ideal animal we are considering. Gamecock (Fig. 259), another winner of the Grand National, and an extraordinarily fine stayer, had all the "shape and make" of a hunter of the highest class. Midshipmite (Fig. 260), who is very smart over a country for three miles and has perfect jumping shoulders, is not very good in his loins and back ribs. The same remark applies to Specs (Fig. 255), who, being longer in the body in comparison to his height, does not approach the race-horse type as nearly as does Midshipmite. During recent years, the best Leicestershire hunter (I am speaking of the middle-weight division) is Mr. H. T. Barclay's Lord Arthur, who has won several steeplechases and ran well in the Grand National, but was beaten for speed. He possesses, in a high degree, the peculiarity, which is invaluable in a saddle-horse (p. 137), of having very powerful limbs in comparison to the weight of his body (contrast the fore legs in Fig. 329 with those in Figs. 283 and 308). Specs (Fig. 255), who is honest, clever, and smart at his own distance and under a suitable weight, is built in the same way, but has not as powerful loins or as "close coupling" as Mr. Barclay's chestnut. Cloister, Gamecock, Lord Arthur, Midshipmite, Specs, and the vast majority of fine hunters and good chasers, are considerably higher at the withers than over the croup. We see this point in Fig. 331, which is a portrait of one of the best weight-carrying hunters that ever crossed the Rugby country; and in Saltry (Fig. 282), a clever and well-bred Irish mare of the old-fashioned sort. As exceptions
Fig. 326.—Mr. H. Savile's Cremorne.

Fig. 327.—Mr. A. A. Aycar's Australian Horse, Bravo.
to this rule, I may mention the names of Franciscan (Fig. 328) and Stepaside (Fig. 333). Franciscan is a beautifully-shaped 15-stone hunter of very high class. Stepaside, an Irish mare, after having been hunted in Ireland, was taken to India, where she showed herself to be the best chaser and hurdle-racer of her time in that country. On contrasting her conformation with that of Franciscan, we shall see that the "middle piece" of her body is too light for the requirements of a fair hunting weight, on a long and fast day. One of the nicest shaped hunters I have ever seen was Captain Williams's Joseph (Fig. 320). As examples of horses with good "middle pieces," I may cite Ormonde (Frontispiece), Cloister (Frontispiece), Franciscan (Fig. 328), Joseph, and Predominant (Fig. 236). If Gamecock (Fig. 259) lacked somewhat in depth at the middle of the back, he amply made up for the deficiency by being, like St. Simon, remarkably round in the barrel (pp. 163 and 164).

Cloister (Frontispiece), whom I have lately had an opportunity of carefully examining, thanks to the kindness of Mr. Duff and Sir Charles Nugent, is in two particulars a very deceptive-looking horse. The great height of the inner angle of his pelvis (p. 208) gives him a false appearance of being slack in the loins, which, in fact, are broad and muscular. His neck is so very light that there is a marked depression between it and his shoulders (p. 183). His shoulder-blades are particularly long; although they are not very well sloped. His shoulders, though muscular, have no superfluous weight about them, as I saw by the fact that there was no undue development of the "saddle muscle" (p. 183), and that his fore legs were not too far apart (p. 171). His withers are high and thin. His fore arms are remarkably powerful. The muscles of his limbs show great development in comparison to the weight of his body, neck and head. His barrel is round (p. 163). He has great power of straightening his hocks, just below which the bone of the leg is singularly broad (p. 211). He shows great bone below the knee, as well as below the hocks.
Allowing for the scars of honourable warfare, his fore legs may be said to be of the type shown in Fig. 294.

As a rule, in "The Provinces," especially where the country is cramped and there is a good deal of plough, as in Cheshire, for instance, the hunters are up to more weight and are more cobby than in Leicestershire. Fig. 330 shows a fine type, as far as conformation goes, of a Cheshire hunter, who, though strong and thick-set, has a sufficiency of speed. For a horse of his build, he has comparatively light shoulders, as we may infer from a front view of his fore hand (Fig. 276), in that he has no undue width between his fore legs.

Love of gambling is, no doubt, the chief cause why, among animals of equally high merit in their own respective spheres of life, race-horses and chasers are more valuable from a monetary point of view than hunters, for were it otherwise, no sane man would spend more money in the purchase of a horse for another man to ride, than in that of an animal for his own riding. I make this remark solely from a desire to emphasise the importance of a study of the "points" of our most valuable all round horse, the hunter; for I am fond of racing as well as hunting, and have no objection to a "mild gamble."

The Heavy Cart-horse—1. The legs should be as short and massive as possible: consequently the animal will be considerably longer in the body than he is high at the withers or at the croup, and he will be deeper from the withers to the brisket, than from the withers to the ground.

2. He should be of great width of body when viewed from behind; and across the chest in front.

3. His muscles, bones, tendons, and ligaments should be as thick and strong as possible.

4. The shoulders should be sloping in cart-horses which do not use their fore legs, to any marked degree, as propellers; and somewhat upright in those which utilise them in that manner (p. 188, et seq.).
Fig. 328. — Mr. H. T. Barclay’s Franciscan.

Fig. 329. — Mr. H. T. Barclay’s Lord Arthur.
THE HACK.

5. The height over the croup should be less than that at the withers (p. 61).

For further remarks on cart-horses, see pp. 254 and 258.

The Harness-horse.—For convenience sake, I use the expression "harness-horse" to signify all horses which go in draught, except the heavy cart-horse. Taking the limits as the racer and Shire horse, I may say that the conformation of the animal should, within certain limits, approach that of the former, or of the latter, according as his work is fast or slow. For remarks on the conformation of the match trotter, see page 261, et seq. The ordinary trapper should be thicker in the shoulders than the saddle nag; and, if he has strong hind-quarters and fair action, he may be pardoned if he be long in the back, slack in the loins, and somewhat flat-sided. For fashionable town work, the harness-horse will, as a rule, require to be either one of the smart small sort, or of the imposing brougham type. The former should have all the good looks and "quality" of a well-bred, middle-weight hack. The latter should measure high at the withers; should have sloping shoulders, so as to have free action in front; and should carry his head high. Owing to the manner in which he is bitted and "checked," his hind action is not taken much into consideration. Between these two kinds of horses, there is as much difference as between a clever bull-terrier and an overgrown, weak-joined mastiff. Fashionable trotting action is far more the result of training than of conformation. For pairs and teams, horses should match in height, colour, general character, action, manners, and mouth.

The Hack.—The chief points about the hack are that he should be "light in front," have sloping shoulders, and sound legs and feet, so that he may be sure-footed and able to stand work; and he should be rather high in front (p. 132). The conformation of his head and neck should be such as to allow him to bend readily to the rein. The action of the hack should be somewhat "high," and should be "true," so
that, when viewed from behind, the near pair of limbs, in the walk, trot and canter, should move in a line parallel to that of the off pair. Action, good looks, and a showy carriage of the head and tail are essentials in the high-priced hack. "Mouth" and "manners" are two other indispensable requisites which do not come within the province of this book.

The Lady's Horse.—A lady's horse should be a good-looking hunter or smart hack, according to the work for which he is intended. He should carry his head and neck particularly well; because his rider, owing to the nature of her seat, cannot keep her hands low down. His fore hand should be inclined to be high, so that his paces may be easy. His withers should not be high and thin; for if they are, they will be liable to be galled on the off side by the saddle. For obvious reasons, he should be up to at least a stone more weight than if intended for a man.

The Cavalry Trooper.—The ideal cavalry horse should (if price had not to be considered) be of the heavy weight (Fig. 331) or thick set (Fig. 330) hunter type. His chief requirements as regards conformation are as follows:—

1. That he should be up to the weight he has got to carry. But he should on no account be too heavily topped for his legs, or for the work he will be called upon to do. His loins, therefore, should be strong, his shoulder-blades long, and his legs should be as short as is compatible with the possession of sufficient speed for military purposes.

2. His legs and feet should be particularly sound and well able to stand work. As he will be called upon at times to go fast and to leap; his back tendons should be more or less parallel with the cannon-bone, and he should have no tendency to undue width of fetlock (see p. 194, et seq.).

3. His fore hand should be light, so that his legs and feet may continue sound, and that he may be able to do his school work properly.
Fig. 330.—Mr. W. H. Walker's Touchstone

Fig. 331.—Weight-carrying Hunter, the property of Mr. Muntz, M.P
4. He should have a good carriage of the head and neck, so that he may be obedient to the rein.

5. He should be a "good doer," and have a strong constitution, which will usually be the case with a horse that has a bright eye; soft, cool skin; deep rounded barrel; full flank; firm, prominent anus; and is well ribbed up.

The Officer's Charger.—A cavalry officer's first charger, with all the useful points of the cavalry trooper, should have undeniably good looks, and a showy carriage of the head and tail, which should not be docked. As he will have to carry less, and will cost considerably more than an animal in the ranks, he should be well bred, and, with a rider of ordinary weight, he should approach the type of a handsome thoroughbred hunter. A second charger should have all the useful points of a first charger; but need not be so good-looking. The colour will, as a rule, depend on regimental regulations. Speaking generally, he should not be less than 15.3. A man at the head of a regiment of cavalry, or of a battery of horse artillery, looks best on a tall horse.

The Artillery Horse.—Artillery horses are divided into those for horse artillery and those for field batteries. As the teams of the former have to manœuvre with cavalry, and also drag their guns, they require to be exceptionally strong, smart horses. The latter, as they are supposed not to go faster than a trot, are stronger and slower horses than those of light cavalry. The wheelers are active, light-built cart-horses. For their work, they need to be somewhat thick in the shoulders, short on the leg, and of considerable weight to stop the gun when the order to halt is given. Their hind-quarters, loins, and hocks should, therefore, be particularly strong. The riding horses of the Nos. 1 and markers of field batteries should be of the light cavalry type.
The Light Vanner, which we meet in vans, 'buses and tram-cars, should be similar in type to field artillery wheelers; in fact, active, light cart-horses that can trot freely and at fair speed.

The Polo Pony.—Handiness and speed, with sufficient staying and weight-carrying power, are the two chief requirements of the polo pony. Consequently, he should be light in front, should carry his head and neck well, have sloping shoulders and particularly strong hocks. The fact of his being slightly “goose-rumped” will be no detriment. The best English polo ponies, such as the once matchless Dynamite (Fig. 237), are animals which, but for an accident of breeding, would have been high-class hunters or brilliant chasers. Mr. E. D. Miller lays down, in Modern Polo, the sound maxim that a polo pony should be by a thoroughbred out of a mare by a thoroughbred.

CHAPTER XXVI.

REMARKS ON VARIOUS BREEDS OF HORSES.

The English Thoroughbred.—I have said so much in the previous chapter on English race-horses, that I shall content myself here with making a few general remarks. As a rule, the chief merits of English thoroughbreds are Speed, early maturity, and the fact of their being "well topped"; their chief defects, weediness, deficiency of bone below the knees and hocks, and uprightness of fore pasterns. Hence, we find among them a far greater number of light-weight sprinters that are incapable of standing much work, than sound stayers which can carry a fair weight, and which will "train on." The English thoroughbred, or nearly thoroughbred, pony, like Predominant, Lord Clyde, Mulberry, Sylvia, Mike, Bustle, Deuce of Diamonds, and Dynamite, is certainly the best of its class in the world, whether for racing or polo. I am inclined to think that in comparison, say, with blood horses in Australia, English thoroughbreds under 15 hands are better than those over that height. If this be the case, the facts that big horses are more liable to become roarers
than small ones, and that roaring is far more common in England than in Australia, would no doubt have an important bearing on this point.

The English Half-bred Horse. — The half-bred English horse, of which we may take the half-bred hunter as the best type, is, as a rule, like the thoroughbred, well topped; but is far too often very poor below the knees, and heavy about the shoulders, both of which defects are generally owing to an attempt to obtain “substance” by the dangerous admixture of coarse blood.

The Shire Horse is a beautiful and essentially English breed, and is the incarnation of equine strength, as we may see by an inspection of such magnificent specimens as Rokeby Harold (Fig. 334), Rokeby Fuchsia (Fig. 335), Bury Victor Chief (Fig. 231), and Chance (Fig. 232). His average height is about 16.2. His proper work is the traction of immense loads at a walk. As regards conformation, he shows a maximum of size, compactness and weight of body, and shortness and muscularity of limb. In Norfolk and elsewhere, a smaller and more active horse, though of the same breed, proves admirably suited to general farm work.

The Suffolk Horse, or Suffolk Punch (Figs. 336 and 337), is the most typical English agricultural horse, being a fast walker and light easy trotter. He ranges in height from 15.3 to 16.2, and, though active, is remarkably compact, shows great bone, and stands on short legs, which, contrary to those of Shires and Clydesdales, carry but little superfluous hair. Chestnut is the only recognised colour for this breed. He is a very hardy horse. No fault is found with him if his shoulders are somewhat upright.

The Cleveland Bay (Figs. 338 and 339) has existed as a distinct type for hundreds of years in the North and
C. Reid, Wishaw.

**Fig. 334.**—**Lord Belper's Shire Stallion, Rokeby Harold.**

C. Reid, Wishaw.

**Fig. 335.**—**Mr. John Parnell's Shire Mare, Rokeby Fuchsia.**
East Ridings of Yorkshire. Formerly, he was used for coaching and agriculture, at both of which he was an equally great success. In ancient days, the roads were so bad and the vehicles were so heavy, that strength rather than speed was sought for in coaching. At farm work, the Cleveland has always distinguished himself by his great activity. With improvements in roads and carriages, breeders of Clevelands have successfully tried to obtain more speed. The Cleveland of to-day is essentially a clean-legged coach horse or light vanner, with blood-like head, full, well-arched neck, sloping though rather thick shoulders (suitable for a collar), and well set-on tail. His good carriage of head, neck and tail makes him a showy harness horse. He has a tendency to be light in the loins, which fact, along with his comparatively heavy fore hand, unfits him, as a rule, for saddle work. The mare stands about 16 hands, the stallion 16.1 to 16.2. The only recognised colour is bay. The action, at a trot, resembles that of a thoroughbred, and is free from “the snap of the knee” of the hackney. At this pace, the Cleveland bends his hocks well, and brings his hind legs under him with great freedom. Tradition points to a Barb cross with Yorkshire cart mares as the foundation of this breed.

**The Yorkshire Coach Horse** (Figs. 340 and 341).—The increase of speed rendered necessary by improved communications, showed the advisability of an infusion of Eastern, and subsequently of thoroughbred blood, into the Cleveland, with the result of the formation of the Yorkshire Coach Horse, which may now be regarded as a distinct type. For detailed information on this subject, I may refer my readers to Vol. I. of *The Yorkshire Coach Horse Stud Book*, which tells us, as instances of the speed and endurance of these animals, that “Dreadnaught, by Old Clothier, won a trotting match for £100, carrying 16 stone 16 miles within the hour; and that Peirson’s Plato trotted 18 miles within the hour, carrying 18 stone.”
The Hackney.—Formerly, the English roadster was represented by two distinct types, namely, the Norfolk trotter and the Yorkshire hackney, which are now merged into the one class of "hackney" (Figs. 342, 343, 314 and 345) after frequent crossing with the thoroughbred. The fashionable hackney (vide Danegelt, Fig. 342) resembles to some extent the thoroughbred by his lightness of body and length of legs; but the heaviness of his fore hand unfit him for saddle work of the hunter or charger kind. His well-shaped head, powerfully developed and commanding neck, horizontal croup, jauntily carried tail, and extravagant action, make him a very showy horse, particularly as his shoulders are oblique, and have a good place for the collar.

Danegelt was not alone a handsome and typical hackney, but possessed the far more valuable quality, in a sire, of being able to transmit to a remarkable extent his best points to his offspring. In Ganymede, he left behind him a worthy son of the highest character.

As a contrast to the fashionable hackney, I give Fig. 346, which shows a very good-looking hackney of the old-fashioned sort. Without appearing to have any cross of the thoroughbred, he looks, to my thinking, the beau idéal of a useful roadster for country requirements in England. I leave my readers to examine his good points, and, to aid them doing so, I give, by way of contrast, Fig. 347, in which the horse is very much of the same class, but differs greatly in slope of shoulder, length of neck, and size and shape of head.

The Exmoor Pony.—Sir Thomas Dyke Acland tells us (see Live Stock Journal, 28th May, 1886) that his father, prior to 1815, had about 500 Exmoor ponies running wild on Exmoor, and that a famous, and possibly mythical, stallion, Katerfelto, was supposed to have infused some fine Spanish or Arab blood into them. He also informs us that Exmoor ponies are miniature cart-horses, with good action, and that they have goose rumps.

To face p. 224.

Fig. 337.—The Duke of Hamilton's Suffolk Mare, Queen of Trumps.
Mr. Charles H. Basset, late Master of the Devon and Somerset Staghounds, writing to Mr. Edward Mucklow, Junr., thinks that there is no breed of pony like the pure Exmoor, of which Sir Thomas Acland and Mr. William Westacott, of Harkridge, are the principal breeders. Mr. Basset says that "these ponies are beautifully shouldered, deep girthed, and with lovely heads; but with the drooping quarters peculiar to the breed, and which, I have been told, are generally seen on all horses and ponies that are bred and reared on hilly and mountainous land. Anyhow, both the ponies and sheep of Exmoor have the same sloping hind-quarters. They are about 10 or 11 hands high, and the colour brown with mealy noses. I am told that Sir Thomas Acland will not keep any other colour, and that it is a sign of a stain in some cross when any other colour but brown appears." Writing to me about Exmoor ponies, Mr. Mucklow says that "they are the foundation of the best polo ponies, mated with a thoroughbred horse, not too big. Ponies bred this way are extraordinary jumpers, and lovely hacks." I may here repeat Mr. E. D. Miller's well-proved rule that the English polo pony of the present day, in order to have sufficient speed, must be by a thoroughbred out of a mare by a thoroughbred. Exmoor ponies have been a good deal crossed in breeding, with the object of increasing their height, which has been obtained with, naturally, some loss of hardihood. Royal Oak (Fig. 348) and Gladys (Fig. 349) are handsome specimens of the breed.

The New Forest Pony (Figs. 351 and 352) is an old English breed, to the improvement of which Lord Arthur Cecil has devoted much attention. They are very hardy, clever little horses, and are good either to ride or drive. They, like the Exmoors, have been much crossed.

The Dartmoor Pony is also an old English breed, and somewhat resembles the Exmoor.
The Clydesdale is a distinct breed of heavy cart-horse that has been long established in Scotland. He is, as we may see from the fine specimens shown in Figs. 353, 354, 355 and 356, a remarkably handsome, strong and active animal. Clydesdale breeders, as a rule, make a great point in obtaining oblique shoulders and sloping pasterns, and seek for ability to walk fast and trot well, with as much strength as possible. The breed has been crossed a good deal with the Shire. Scotch breeders will no doubt keep the Shire type in their minds; for weight means money in the cart-horse market.

The Shetland Pony (Figs. 234 and 357) is an extremely hardy, handsome, and strong pony of from 10 to 11 hands high.

The West Highland Pony (Fig. 358) is another indigenous Scotch pony of great hardiness and strength.

The Welsh Pony varies greatly in height and conformation. Many of them have a good dash of hackney blood, and make very useful trappers. An immense number of these animals may be found in tradesmen’s carts of the light sort throughout England.

Australasian Horses.—The special good points of Australian, Tasmanian, and New Zealand horses, from a saddle point of view, are their excellent flat shoulders, light necks, well-shaped legs, and sound feet. Their loins, barrel, and croup are not, as a rule, as good as those of English horses; but they are able to stand more work. Animals that are brought up on extensive “runs” till they are, say, four years old, develop better shoulders and sounder legs and feet than those which are “taken up” early; although, other conditions being equal, they may, perhaps, not be as neatly “topped.” Their light fore hands and good shoulders make the Australasian horses clever jumpers. The Colonial
Fig. 338.—*Cleveland Stallion, Luck's All*, the property of Mr. H. C. Stephens, M.P.

Fig. 339.—*Cleveland Mare, Madam*, the property of Mr. H. C. Stephens, M.P.
animals, taking them all round, have more thoroughbred blood in them than their English cousins.

The Antipodes, as far as I can judge, are far more suitable for the production of thoroughbreds with large bone and substance, than is England. Hence we find, in these colonies, a comparatively large number of animals of the weight-carrying hunter and charger type which have little or no stain in their pedigrees. On the other hand, although thoroughbreds in England have a greater tendency to "run light" than in Australasia, they certainly show more "quality" than those of any other country. Without wishing in any way to dogmatise, I would venture to say that the Colonies are capable of producing more useful saddle-nags and cavalry troopers than Europe; but not as high-class "sprinters." As an exception to their general utility for Army purposes, I think that better field artillery horses, and especially field artillery wheelers, which require a strong admixture of cart blood, can be obtained in England, than in Australia. As a proof of deterioration in racing "quality," I may mention that, up to the present, the produce of imported sires has, as a rule, been more successful on the Australian turf than that of Colonial-bred sires, of which the best has been Yattendon, whose two most distinguished sons at the stud were Grand Flaneur and Chester, both out of imported mares. The best Australasian sires have been imported horses, such as Panic, Musket, Fisherman and St. Albans. The same rule appears to hold good in America, if we may judge by what the Spirit of the Times says in the following extract: "The success of imported English sires within the past twenty years, beginning with Leamington, has certainly impressed many breeders with a belief in their superiority. Glenelg, Australian, Bullet, King Ban, The Ill-used, Great Tom, King Ernest, Bonnie Scotland, Rayon d'Or, Prince Charlie, Phaeton, Eclipse, St. Blaise, etc., have well-nigh driven the native stallions into exile. Virgil may be said to have been the only stallion who was native bred on both sides of his pedigree, and who has held his own
against the imported horses. Longfellow, Spendthrift, Enquirer, Eolus, King Alfonso, and other successful native sires, were the sons of imported horses. The English mares have also succeeded in a great degree."

As long as Australia and America have to obtain fresh infusions of blood from England, to keep up the excellence of their respective breeds of race-horses; so long should no jealousy, as regards horses, exist between the mother-country and her offspring, who should regard their state of dependency on her, as one of her strongest claims on their affection and support.

Australasian race-horses at long distances are probably as good as any horses in the world. The performance of Carbine (a New Zealand son of Musket) in winning the Melbourne Cup, two miles, with 10 st. 5 lbs. up, compares not unfavourably with the most brilliant victories of Ormonde, Isonomy, or St. Gatien. In the Colonies there are many smart racing ponies, like Glengary II., Little Wonder (New Zealand), Mayflower, and Jeannette; but they are not, as I have already remarked, as good as the best in England and Ireland.

The Australian race-horse, Bravo (Fig. 327), by Grand Flaneur out of The Orphan, won the Melbourne Cup in 1889, when in receipt of 21 lbs. from Carbine. When I took his photograph, he was about half-trained, and was consequently somewhat lusty. To judge of him as he was standing for his portrait, he appears to have been a trifle longer in the body, than he was high at the withers, from which fact we might infer that he was not a race-horse of the highest class. He had good shoulders, long neck, short back, and good depth at the centre of his back, and was consequently a fine stayer. His hocks were not as straight as those of Ormonde (Frontispiece), Persimmon (Fig. 322), or St. Simon (Figs. 9 and 229).

Romance (Fig. 270) is a handsome Australian horse of the light or even middle weight hunter or charger type. He won several races over hurdles and on the flat in

AMERICAN TROTTERS. 261

Australia and India; but among inferior company. His shortness of leg, as compared to his length of body, precludes the possibility of his being gifted with a fine turn of speed. Though no race-horse, he is perfectly shaped as a fast hunter. He has a short back, long "rein," and particularly strong, well-formed legs. His good shoulders and light head and neck are valuable jumping and galloping "points." His best points of speed are, no doubt, his straight hocks and powerful gaskins.

The horse shown in Fig. 271 belongs to a common type of underbred Australian horse, which makes a good remount and useful slave. As a rule, these horses are well fitted for saddle; for their fore hand is comparatively light and their legs good.

The Norwegian Pony is a distinct breed that has been long distinguished by its hardiness, activity, and general usefulness. A good representative of these small horses, and fast trotter, is given in Fig. 359. A half-bred Swedish hunter is shown in Fig. 360.

The Iceland Pony (Fig. 307) is a diminutive, good-looking breed that manages to exist under most severe conditions of privation and cold.

American Ponies.—Figs. 238 and 362 show us good types of American polo ponies.

American Trotters.—According to Mr. Francis A. Foster, of Boston, who very kindly writes to me on the subject, the trotter (Figs. 363, 364, 368, and 374), compared to the thoroughbred, has a large head; short and thick neck; deep and short body in comparison to his height; broad chest; low withers; thick shoulders; and is broad, as viewed from behind. In fact, he has more bone and muscle all round than the race-horse of English blood. His chief characteristic, as regards conformation, is the shortness and depth of his
body as compared to his height. He is, as a rule, a smaller horse than the thoroughbred. Trainers of trotters prefer small horses; for they find them more lasting than big ones. I am inclined to think that the pelvis of the American trotter is more sloping than that of the thoroughbred; a peculiarity which would cause him (1) to be shorter in the body; and (2) to have his hind legs more under him than would be the case if his pelvis were more horizontal. The best American trotters vary in height, as a rule, from 15 hands to 15.2. Taller trotters seldom prove to be good campaigners. The following is a list of the respective heights of some of the most famous American trotters:—

The stock of the Hambletonians are very irregular as to size. The Mambrino Chiefs are tall and leggy. The Morgans keep close to 15 hands.

The characteristic difference between the conformation of the American trotter and the thoroughbred, as regards the proportion between the length of body (or rather, the length from hip joint to point of shoulder) and length of limb, is shown not only by actual measurement, but also by the fact that many match trotters cannot go fast without "interfering" to such an extent that they are obliged to be exercised habitually in specially made boots ("scalpers"). Setting this and other not so pronounced differences aside, the fact remains that the American trotter, at least as regards "quality," has shown a gradual approach to the

thoroughbred. Originally sprung from horses which possessed the all-important gift of trotting, although in many cases of coarse blood, they were at first but little removed from what we might call "light harness horses." By careful selection, good management, and, perhaps, the judicious infusion of English racing blood, the conformation of the trotter, from a speed point of view, has improved immensely, as we may see from the following record times for one mile:—

Some strains of American harness-horses produce, indifferently, trotters or pacers, which is a peculiarity that is not found among true trotting breeds of other countries, such as England or Russia. It appears that in these American cases there is always a cross, more or less remote, of pacing blood. Pacers never come from stock in which there is no pacing blood.

American trotting blood is eminently suited to give speed and useful trotting action to all light harness horses. I believe that this cross with the Hackney, under favourable conditions, is productive of a harness horse of showy presence and fine speed. Although conformation, no doubt, plays a certain part in the result, I am inclined to think that the wasteful knee action and consequent tendency to roll from side to side, too often exhibited by the Hackney when going at his highest speed, is chiefly due to training.

When we consider that, in modern times, no race-horse with a stain in his pedigree has ever gained first-class honours on the turf, and that a considerable admixture of coarse blood is no bar to high trotting merit; we may not unreasonably conclude that the gift of trotting lies more in the brain than in the muscles.
South African Horses.—The ordinary horses of the Cape Colony, Transvaal, Orange Free State, and Natal show a fair amount of "blood," with a dash of the Arab, and have very good legs and feet. They are, however, for the most part "weedy." Although they are admirable "slaves" with a light weight, or with but little to draw, they are quite unsuited for military purposes. Those which are up to the weight of a trooper, or fit to take their place in an artillery team, would, at an average price of £35 or £40, be too slow for cavalry or horse artillery work. The weight-carrying hunter type of horse is practically unknown in South Africa. The success on the turf of locally bred horses, like Prosecutor, proves that the country is capable of producing good race-horses. The freedom in which stock are raised there, undoubtedly accounts for the excellence of their limbs. The chief native breed, the Basuto pony, is a remarkably hardy animal, with capital legs and feet; but as he is rather short on the leg, he is deficient in pace. Indeed, South African horses, except those that are thoroughbred, are, as a rule, very slow; a fact which is no doubt due, in many instances, to their loins being weak, their gaskins poor, and their hocks being too much bent. South African breeders are much handicapped by outbreaks of "horse-sickness" and by want of water. With the exception of these drawbacks, the country, especially in the Colesberg district and Orange Free State, is admirably suited to the production of good horses. South Africa is singularly wanting in smart ponies, such as those fit for polo. In this respect it forms a marked contrast with England, Australasia, India, and Arabia.

South American Horses.—In the Argentine Republic many good thoroughbreds are raised by Mr. Kemmis and other breeders. I have no means of "drawing a line" between them and English or Australasian horses, except the fact that Camilla, the aged daughter of Phénix, with 32 lbs. the best of the weights, beat the Australian plater, The Wild Oat, and five others at Calcutta in December, 1890. Neither
Fig. 344.—Mr. Tom Mitchell's Hackney Stallion, Ganymede.

Fig. 345.—Hackney Mare and Foal, the property of Sir Walter Gilbey.
Camilla nor The Wild Oat, at the time, were good representatives of their respective classes; so the result of the race is no criterion to go by. The common Argentine horses, if somewhat wanting in blood, are of the sturdy and useful sort. The country seems well suited to the production of excellent stock.

**Arab Horses.**—My friend, the late Shaikh Esa bin Curtas, always maintained that the best Arabs did not, as a rule, exceed 14.1\(\frac{1}{2}\) or 14.2 in height. Ali bin Abdoolah, another Arab friend of mine, and of nearly as great experience as the late Shaikh, likes them bigger. From a galloping point of view, judging by the Indian records of the last half century, there is not much to choose either way; the balance of weight being probably with the big Arabs, like Child of the Islands, Raby, Lucifer, Marquis, Sherwood, Euphrates, and Euclid. Yet with such good fourteen-handers as Anarchy, Chieftain, Shere Ali, and Turkish Flag, who, in their time, were second to none in their own class; the fact remains, that for the attainment of galloping excellence, an Arab need not exceed 14.1\(\frac{1}{2}\) My own impression is that among the Arabs sent to India for racing are to be found many of the best and highest caste horses bred in the Desert. This opinion is in accordance with that often expressed to me by experienced Arab dealers whose friendship I have enjoyed. Also, poor Colonel Valentine Baker, whom I knew in Cairo, and who had an intimate acquaintance with Eastern horses, told me that the best Arabs were sent to Bombay, where new importations, if of really high character, readily fetch from £200 to £300 a-piece. We may infer from the foregoing remarks, that the Arab horse is, according to our Western acceptation of the term, a pony. Even restricting him to this class, I feel confident that the best Arab that ever lived, no matter what his height, was inferior, from a racing point of view, to a first-class English or Australian pony of fourteen hands. The English fourteen-hand pony mare, Skittles, the property of Captain Mowbray, of the Black Watch, beat
REMARKS ON VARIOUS BREEDS OF HORSES.

in a two-mile match at Cairo, in 1886–7, the Arab Haddeed in a common canter, when giving him 7 lbs. He was looked upon in Egypt as an extraordinary good Arab. Mr. Kelly Maitland’s Australian 13.2 mare, Fleur de Lys, several times proved herself as fast as any Arab in India for ½ mile. Taking the time test, which has been applied with great precision to the running of Arabs, we find that their performances in India have been much inferior to those accomplished by the English ponies, Lord Clyde (formerly belonging to Mr. John Watson), Predominant (Fig. 236), and Labby (by Wisdom), and by the Australian pony mare Achievement, none of whom exceeded fourteen hands in height. Although Arabs are not race-horses, they are excellent hacks, and excel particularly as light cavalry troopers. In these respects the small Arab, not exceeding 14.2, is, as a rule, undoubtedy better than the bigger Arab. A son of the Desert of the best type has a handsome and intelligent head, with broad forehead, large, “kind” eyes, straight or concave line of the face, large nostrils, well carried ears, lean and wide jaw. His neck, if somewhat coarse, is fairly long and is well set on to his head, which is carried bravely. His shoulders are well sloped, although they often err, from a galloping or jumping point of view, on the side of thickness, and his breast is not too broad. He has capital legs and feet. His withers are often somewhat low and thick. His loins are flat, broad, and powerful. For roundness of barrel and length of back ribs, for levelness of croup, and for beautiful carriage of the tail, he is certainly without equal among horses. He is not unfrequently higher over the croup than at the withers, which, in that case, will have a consequent tendency to be unduly low and thick. I do not think that his hocks and gaskins are as good as those of well-bred English or Australian animals. In justice to the Arab, I must point out that the heaviness of his fore hand, as compared to that of the English thoroughbred, is due to the large size of the muscles which attach his shoulders to his chest, and which draw the fore limbs forward and backward.
Fig. 346.—Old Fashioned Roadster.

Fig. 347.—Roadster.
The comparatively large development of the muscles of his fore hand and loins makes him a good weight carrier for his size. The common statement, that Arabs have bad shoulders, has evidently been made by persons who do not know that the kind of shoulders which might be very good in one class of riding horse, might be equally bad in another kind of saddle animal. The grandly shaped barrel of the Arab plainly indicates that he has clear wind, strong constitution, and that he is a good "doer." Fig. 370 shows us Blitz, the best 13.1 Arab pony that has ever run in India; but he was not as good as the English pony Mike, who was about half an inch the smaller of the two.

The more an Arab exceeds, say, 14.2 in height, the more inclined is he to be long in the leg, light in the loins and flanks, and flat-sided.

The term Gulf Arab (Figs. 263 and 361) is applied to horses, which, though not desert born, have a dash of Arab blood, and which have been imported to Bombay from the Persian Gulf. They stand about midway between the true Arab (Fig. 370), and the Cabuli (Fig. 264). I believe that, as a rule, they are either Persians, or have been bred in the Euphrates valley.

**East Indian Horses.**—The native horses of India are of the smart, wiry sort. As a rule, they are best when they do not exceed 14.1 or 14.2; for the more they overtop this height, the "weedier" do they become. Having light fore hands and well-sloped shoulders, they are clever and jump well. They have excellent feet. Their legs, though capable of standing a great deal of work on hard ground, are often, from errors of breeding and bringing up, misshapen; so that turned-out toes, calf-knees, cow-hocks, and sickle-hocks are of frequent occurrence among them. Generally, they are flat-sided and light in the loin. Consequently, they are poor weight carriers, and bad stayers at fast paces; but are marvellously good at enduring fatigue and privation. The best of them make capital light cavalry horses up to, say,
Although they are not as strong or as good-looking as Arabs, they are probably harder and better suited to endure hunger and thirst. Many of them, especially if they have a dash of English or Arab blood, have a fair turn of speed, and consequently make good pig-stickers and polo ponies. Indian racing ponies, which have a strong infusion of English blood, are, speaking generally, about 14 lbs. worse than Arabs of the same height, and particularly so over long distances. At fourteen hands it would be difficult to "bring them together" with English ponies in a race for, say, a mile. Without the constant importation of fresh blood from England, it is impossible in India to breed horses fit for racing, or for the requirements of English cavalry and artillery: even then, the results are very poor. Good as Tangri, Minden (Fig. 269), Engadine, and others of General "Ben" Parrott's breeding have been in their own class and against Arabs, their form has been but little better than that of fourteen-hand English ponies.

Minden (Fig. 269) was a famous "country-bred" race-horse in India, among his own class, which is not within "measureable distance" of that of English £50 selling platers. Viewed as a smart saddle-nag, I must say that Minden looks a nice-shaped horse. He has capital shoulders and a good "middle-piece." I may add that he was in training when I took his photograph. The fact of his being longer in the body than he is high at the withers or at the croup, points to deficiency of speed.

Fig. 377 shows us a typical Kathiawar mare. She is a "three-cornered" animal, but having been brought up among rough surroundings, is capable of enduring much privation and hard work; though necessarily slow on account of her body being much longer than she is high at withers or croup. Her body is also very long compared to its depth. She is "calf-kneed," "sickle-hocked," and slightly tied-in below the hocks. As compensations, her shoulders are fairly well shaped, her fore arms and
Fig. 348.—Mr. Edward Mucklow, Junr.’s Exmoor Pony Stallion, Royal Oak.

Fig. 349.—Mr. Edward Mucklow, Junr.’s Exmoor Pony Mare, Gladys.
gaskins are strong; and her "bone" below the knees is good.

Under the present heading we may put Cabuli (Fig. 264), Baluchi, and other Trans-Indus horses, which are largely used in India, and which, though stouter and shorter on the leg, are neither as smart nor as hardy in hot climates as the "country-bred." We might consider them as intermediate between the East Indian horse and the Mongolian pony.

**Burma and Manipuri Ponies.**—The so-called Burma pony (Fig. 378) is chiefly bred in the Shan Hills. He rarely exceeds 13.2, and is probably at his best when about thirteen hands high. He is a grand weight-carrier, jumps well, and is very hardy, though slow. The ponies of Manipur, which has been the home of polo for many centuries, are closely akin to those of the Shan States; but are smaller, and smarter for their size. These two kinds of ponies appear to belong to a distinct breed, which seems to have no relationship with ponies of any other country, except, possibly, with those of Sumatra and Java. The Burma pony is sometimes called a Pegu pony. I may say that in the vast extent of country from Rangoon to Mandalay, there are no good native ponies bred.

The body of the Burma pony has great depth in comparison to its length. For a saddle-pony, he has a nice head and neck, and fair shoulders; but his croup is too drooping. He is much better "topped" than he is below his elbows and stifles. His fore arms and gaskins are poor, and he has sickle hocks. As might be expected, Burma ponies, of which this one is rather a good specimen, are strong for their height, but slow.

**Sumatra and Java Ponies.**—The strongest ponies for their size I have ever seen, are those of Deli (Sumatra). Their average height is about 12.2. They have handsome heads set on to high-crested necks, are full of spirit, and
are simply balls of muscle. The capable and light-hearted way in which one of these grand Lilliputs can trot away with a four-wheeled carriage containing five or six heavy men, is a sight worth going many miles to see. Acheen, which is in the north of Sumatra, has a good breed of ponies. The Java pony, though a relation of, is inferior to the Deli pony.

**Mongolian Ponies.**—Under this broad heading I would class a breed of ponies which is found in the high-

![Fig 350 — The China Pony, Teen Kwang](Drawn from a photograph)

lands between Siberia and the Himalayas, for I can see no distinctive difference between the ponies of Bhootan, Spiti, Yarkund, and Mongolia, with all of which I have had more or less acquaintance. The so-called China pony is bred in and sent from Manchuria to China, usually via Tientsin. They have thick-set bodies, short, sound legs, capital feet, fairly good shoulders for a saddle, and are hardy and sure-footed. They average about 13.1 and are very slow. In China, Mongolian ponies are used extensively for racing, of course, among themselves, and with
Fig. 351. - New Forest Pony Stallion, the property of Lords Arthur and Lionel Cecil.

Fig. 352. - New Forest Pony Mare and Foal, the property of Lords Arthur and Lionel Cecil.
excellent results, as far as sport is concerned, for the entries are large, and the pretensions of the candidates pretty even. It has been found that it is no advantage, from a racing point of view, for a Mongolian pony to exceed 13.2. The once matchless Teen Kwang (Fig. 350), who may be regarded as the Ormonde of the Far East, was a little under that height. An English, Australian or Arab 13.2 racing pony could give, in a mile race, about 150 yards start to a first-class China pony of the same height, at even weights. The pony of the Himalayas, Yarkund, and Chinese Tartary is a splendid weight-carrier, and is matchless for enduring fatigue and privations in a cold and desolate country.

Corean Ponies.—The indigenous pony of Corea is an extremely small animal, often not more than nine hands high. He is very handsome, being built on fine and graceful lines, in fact, he looks like an Arab, or like the Iceland pony in Fig. 307. Despite the smallness of his size, and the slightness of his build, he is capable of doing a good deal of hard work. He seems to be of quite a different breed from the Manchuria pony.

Japanese Ponies are weak-bodied, long-legged animals of about fourteen hands high. In the main island are used a large number of imported Mongolian ponies, which, being thick-set and short on the leg, differ a great deal from the indigenous animals, the best of which come from the province of Namba. There are several half-breds which have been produced by a cross with English or American blood, and which show an advance in height and speed as compared with their local ancestors and with Mongolians. The Nippon Race Club has a very nice course on the Negishi Hill, which is about three miles from Yokohama. In the northern island (Hokkaido or Zezo) there is a distinct breed of ponies, which are weak and weedy.
CHAPTER XXVII

WILD HORSES.

Wild Horses in Australia and America—Tarpan—Prejevalsky's Horse

Wild Horses in Australia and America.—In Australia, there are many herds of wild horses, which are descended from escaped or "turned out" domesticated animals. Those of America are usually supposed to be of a similar ancestry. This idea is, however, open to doubt, for fossil remains of horses like unto those of the present time, or closely akin to them, are to be found nearly all over North and South America. Considering their former abundance in prehistoric times, and the favourable conditions for equine life which appear since then to have existed in the New World, it seems highly improbable that there were no horses on that continent at the time of the Spanish discovery. This doubt is still more strengthened by the fact that Northern Europe was in communication with North America hundreds of years before Columbus first sighted the Bahama Islands.

Tarpan.—"The nearest approach to truly wild horses existing at present are the so-called Tarpan, which occur in the steppe-country north of the Sea of Azoff, between the river Dnieper and the Caspian. They are described to be of small size, dun colour, with short mane, and rounded, obtuse nose" (Sir William Flower). The Russian naturalist, Poljakof, states that they are mouse-coloured, lighter coloured under the belly than elsewhere, and that their legs are black below the knees and hocks.
Fig. 353.—Mr. P. Crawford’s Clydesdale Stallion, Prince of Carruchan.

Fig. 354.—Mr. R. H. Walker’s Clydesdale Mare, Zeynab.
Prejevalsky's Horse, which has been found in Central Asia near Zaisan and in the desert of Dzungaria, is described by Poliakof ("Annals of Natural History," 1881, p. 16, et seq.) as intermediate between the horse and the ass. Like the former, it has castors (chesnuts) on its hind legs as well as on its fore extremities; and, like the latter, it has an erect mane and no forelock. It has no stripe down the back. Its tail is bushy, being furnished, like that of the horse, though not to the same extent, with long hairs from the root of the tail. Poliakof states that it is of a dun colour, has a yellowish tinge on the back, and is lighter coloured under the belly than elsewhere. It is supposed to be indigenous to Central Asia.

All kinds of wild horses are smaller and inferior to domesticated animals, in every useful particular, except, perhaps, in the quality of their hoofs and in the soundness of their constitutions.
CHAPTER XXVIII.

ASSES.

Differences between the Ass and Horse—Hybrids between the Horse and Ass—Varieties of Asses—The Domestic and Abyssinian Wild Ass—The Onager—The Kiang—The Mountain Zebra—Burchell's Zebra—Chapman's Zebra—The Grévy or Somaliland Zebra—The Quagga—Points of the Ass.

Differences between the Ass and Horse.—The following are the chief differences between the two animals —

1. The ass has castors (p. 192) only on the fore legs.

Chauveau is of opinion that the castor is the rudiment of the thumb, or rather first digit. Against this idea there are the following facts:—

(a.) The castor has no special connection, bony, ligamentous, or otherwise, with either the bones of the knee or those of the hock. As, in the evolution of the horse, the wasting away of the digits (p. 289, et seq.), which have either disappeared or have become rudimentary, began from below, it is unreasonable to assume that a vestige of the first digit should have remained after all trace of its metacarpal or (as the case may be) metatarsal bone had been lost.

(b.) The second and fourth metacarpal and metatarsal bones still remain strongly in evidence, yet their digits have entirely vanished.

(c.) The castors are situated below the hock and above the knee. In the onager I have seen them much nearer the elbow than the knee.

I think the foregoing facts are sufficient to prove that the castors are not rudiments of the first digits. I have no theory to offer respecting their origin.
C. Reid, Wishaw.

Fig. 355.—Lord Londonderry's 4-year-old Clydesdale Stallion, Holyrood.

C. Reid, Wishaw.

Fig. 356.—Mr. John Gilmour's Clydesdale Mare, Moss Rose.

To face p. 274.
2. The ass has a tufted tail, somewhat like that of an ox, erect mane, and no forelock. The horse has a bushy tail, drooping mane, and a forelock, when they have been allowed to grow. The difference in the mane is due to the length of the hairs of the part. In the horse, the hairs of the tail grow long from the root of the dock. In the ass, they do so only as they approach the end of the tail.

3. Veterinary anatomists state that the ass has five loin vertebrae, and the horse six (p. 24), unless in some very exceptional cases, when he may have five. If we examine the skeleton of the mountain zebra (Fig. 257) which is in the Museum of the R.C.S., Lincoln's Inn Fields, we shall, however, see that it has six loin vertebrae. The skeleton of the famous race-horse Orlando, which is in the same building, has only five loin vertebrae. I have never heard of an instance, in the domestic ass, of the number of these bones exceeding five. I do not know their normal number in zebras.

4. In the horse, the lachrymal duct, which is the canal that conveys tears from the eye on each respective side into the nostril, has its opening near the inferior commissure of the nostril, and on the line of union between the dark-coloured skin and the pink mucous membrane. In the ass and mule, it is situated at the inner face of the outer wing of the nostril. This orifice is sometimes double.

5. In the ass, the false nostril extends higher up than in the horse.

6. The male ass has two rudimental teats in the form of small tubercles. They are absent in the horse.

7. The ass brays; the horse neighs.

8. In the ass, the deep depression at the base of the epiglottis is covered by a thin membrane, which is capable of vibrating, and which is wanting in the horse. Its presence may have some influence in causing the voice of the ass to differ from that of the horse. I may explain that the epiglottis is a cartilage that acts as a door to the larynx, which is the organ of voice, and which forms an opening into the windpipe.
9. The ass hardly ever has any irregular markings on its coat, such as a "star," "blaze," "reach," or "stockings," all of which are very frequent among horses. A small star, on one or two occasions, is the only mark of the kind I have ever seen in the ass. At the same time, I must state that I have not had much experience among these animals.

10. I believe I am correct in saying that the colour of the ass is never of a bright bay, chestnut, red or blue roan, or nutmeg grey. I have seen mules of an iron-grey colour; but have not observed it in the ass. This conservatism in colour and freedom from irregular markings, shown by the ass, is very remarkable; considering how greatly the coat of the horse varies in this respect, and that the ass has, in all probability, been longer under the influence of domestication than the horse.

11. As regards conformation, I may say that the ass differs from the horse, chiefly, by its greater height over the croup, as compared to that at the withers, and by the narrowness, uprightness, and concavity of its hoofs. The excess of height at the croup tends to make the withers of the ass appear unduly low (p. 167). The spines of the vertebrae at the withers are only a little shorter in the ass than they are in the horse. As a rule, horses are higher at the withers than they are at the croup.

12. The horse has a thick strong dock to his tail; the ass, a thin, lissom one.

13. The horse, on each side of his croup and covering his pelvis, has, underneath and closely adhering to the skin of the part, a thick and extremely dense layer of connective tissue, which is so close and hard, when the skin has been tanned and dried, that it looks like horn. These two patches of thickened skin are separated from each other about four or five inches apart, so that there is a strip of skin of ordinary thickness running down the croup towards the tail. These pieces of skin are utilised, chiefly, for the manufacture of long boots for foreign cavalry officers, by curriers, who dress and pare down the "shell," or hardened layer, until it is almost as
C. Reid, Wishaw.

Fig. 357.—Lord Londonderry's Shetland Pony, Laird of Noss.

Fig. 358.—Lords Arthur and Lionel Cecil's West Highland Pony, Highland Laddie.
smooth as glass, and can consequently take the brilliant polish which is greatly esteemed by these beaux sabreurs. I need hardly say that the leather which is thus employed, is worn inside out. It is both air and water tight. The "shell" is connected to the skin so closely that the two form one piece; although their respective consistencies are different. If a section be made through the hide, their line of union may be readily seen. In the ass, the "shell" is not confined to the skin that covers the pelvis; but also extends over the ribs, which are consequently not as sensitive to the effects of blows as are those of the horse. I may point out that the tendency which a horse has to turn his rump, as the least sensitive part of his anatomy, towards falling rain, cold currents of wind, etc., appears to be due to the feeling of protection to that part, which the presence of the "shell" on each side gives him.

Huxley remarks that asses form a distinct species from horses; because "all asses have tufted tails and have callosities only on the inner side of the fore legs. If animals were discovered having the general characters of the horse, but sometimes with callosities only on the fore legs and more or less tufted tails; or animals having the general characters of the ass, but with more or less bushy tails and sometimes with callosities on both pairs of legs, besides being intermediate in other respects, the two species would have to be merged into one. They could no longer be regarded as morphologically distinct species, for they would not be distinctly definable one from the other." When Huxley wrote this, he was evidently unaware that the horse has not invariably callosities on all four legs (p. 193).

**Hybrids between the Horse and Ass.**—Neither the mule (the produce of the jackass and mare), nor the hinny or jennet (the cross between the horse and the she-ass), is fertile, either among themselves, or with other members of the horse family. Those animals which have been mistaken by superficial observers as fertile mules, have been, I venture
to say, in most cases the offspring of mares that have
previously bred to donkeys, and have endowed their young
with some of the characteristics of their former asinine lovers.
Both the mule and the jennet respectively "take after" their
dam in size; and their sire, in appearance and disposition.

I know nothing respecting the question of the fertility of
the respective crosses between the different kinds of asses,
true or striped.

**Varieties of Asses.**—These animals may be divided into
the true or whole coloured asses, including the domestic or
Abyssinian ass, the onager, and the kiang; and the striped
asses, comprising the mountain zebra, Burchell's zebra, Grévy's
zebra, and the quagga.

**The Domestic and Abyssinian Wild Ass (Equus
asinus, Fig 272).**—The domestic ass or donkey is, with hardly
any doubt, identical with the handsome and speedy wild ass
which is found in North-eastern Africa, and which is known
as the Abyssinian wild ass. The chief characteristics which
distinguish it from other asses is the possession of a nearly
vertical black stripe running down the shoulders, from the
front of the withers, and the narrowness of the stripe down
the back. These two stripes, which are, as a rule, only from
a half to three-quarters of an inch wide, make the well-
known cross. Sir William Flower states that the shoulder
stripe is "sometimes double, and not infrequently altogether
absent." I believe the stripe down the back is now and
then wanting. It is not uncommonly seen among native bred,
and especially dun-coloured, horses in India. This wild ass
is of a light mouse colour except on the muzzle, under part
of the body, and inside of the legs, which are more or
less white. Its coat, particularly in the case of the domestic
ass, may vary from white to a very dark brown, or even
black, with tan "points." Both in a wild and tame state, it
frequently shows dark horizontal stripes on its fore arms. It
resembles the mountain zebra in having very large ears,
Fig. 359.—Mr. Helgesen's Norwegian Pony.

Fig. 360.—Mr. Helgesen's Half-bred Swedish Hunter.
and a very large head compared to the length of its body. From ancient Egyptian records we learn that this ass was employed for domestic purposes in Egypt many centuries before the horse was known in that country. Its introduction into Europe, however, has been comparatively of recent date. It does not appear to have been known in England before the time of the Saxons, and did not come into general use until the beginning of the seventeenth century. The horse, as we all know, was employed by the ancient Britons, even for purposes of war, at the time (55 B.C.) when Caesar landed. The donkey used by native washermen in India is the smallest and most miserable of its kind. It is often not more than eight hands high, and, from overloading at a far too early age, its hocks frequently are so much turned in that they rub against each other at every step, even when the animal is at liberty. In countries like America and Spain, where care has been bestowed on the breeding of this ass, it may be found as big as an ordinary saddle horse, and proportionately strong.

The donkey associates itself to man as readily as does the dog, and, unlike the horse, evinces little or no inclination to return to a wild state of life after it has become domesticated. It is interesting to note that this ass, which is characterised by a stripe (sometimes two stripes) down the shoulder, and frequently by horizontal stripes on the fore arms, is a native of the country (Africa) in which zebras are indigenous.

The Onager (Equus onager, Fig. 273).—The wild asses which are found in Syria, Arabia, Persia, Baluchistan, Turkistan, Afghanistan, and Kutch (in India), resemble each other so closely that they may be classed under the one heading of “onager,” which is the term usually reserved for the Indian and Persian wild ass. It is lighter in colour and longer on the leg, in comparison to its length of body, than the Abyssinian variety. It is generally of a light mouse or ash colour on the head (with the exception of the muzzle),
and on the upper parts of the neck, shoulders, back, and quarters; and more or less white on the muzzle and under part of the neck, chest, and belly, and on the legs. Sometimes the colouring is so faint that the animal's coat looks almost of a silver white. It has not, or only to a slight extent in exceptional cases, the cross stripe on the shoulders.

There is a broad stripe, about five inches wide at the croup, down the back, nearly similar to that of the Burchell zebra (Fig. 367). Adults are from twelve to thirteen hands high at the withers. Its ears are not quite as long as those of the Abyssinian wild ass. It is handsome, very fast, and extremely difficult of approach.

The Kiang (Equus hemionus, Fig. 384) is the wild ass of Thibet and Tartary. It seems to be identical with the onager, except that it is different in colour, more heavily built, on shorter legs, and that the stripe down the back is narrower. The colour of the kiang is a rather light brown, which is darker and redder than the light mouse colour of the onager; but is not red enough to be termed a bay. This ass is about thirteen hands high. It is far less wary than the onager, and consequently falls a ready prey to the cockney sportsmen who invade its domains in the high table-lands of Thibet.

The Mountain Zebra (Equus zebra, Fig. 257) has a more tufted tail, a scantier mane, longer ears, and a larger head for its size than the Burchell zebra. As far as my experience goes, it has a thicker neck, and its legs, especially as regards the back tendons and suspensory ligaments, are not as well suited to civilized requirements as those of the Burchell zebra. The male, at least, appears to have a rudimentary dewlap. Its stripes are black or dark brown, on a white ground. The most distinctive difference between the arrangement of its stripes and those of the Burchell zebra, is the existence of a number of transverse stripes, which run across the top of its croup and across its tail. In some instances, this zebra is white on the underneath
Fig. 361.—The Gulf Arab Polo Pony, Spec.

Fig. 362.—The Hon. W. Anson's Texan Polo Pony, Rondo.
part of the body. With this exception, it is distinctly marked all over the body, even down to the coronets, with black and white stripes. It is indigenous to the southern part of Africa. I believe it has not been found north of the Vaal River. At present (1896), it is met with in a wild state only in a few mountain ranges in the southern part of Cape Colony, where it is preserved. There is a herd of these zebras preserved on a farm near Craddock, which is a small town in the eastern province of Cape Colony. It is much wilder and more intractable to handle than the Burchell zebra. I have been told that on different occasions it has been successfully "inspanned" in South Africa, although I have not heard of its having been put into draught between the shafts. I may point out that the steadiness of an animal is far more severely tested by having to bear weight placed on its back by the shafts than by merely pulling against breast harness, or even against a collar, in a "span;" and by going in saddle than by any kind of harness work. The height of the mountain zebra, when full grown, is about twelve hands.

Burchell's Zebra (Equus burchellii, Fig. 258) differs from the mountain zebra in being taller (its full height is about 13.1 or 13.2), having a longer and thicker mane, a more bushy and less tufted tail, smaller ears and a smaller head in comparison to the length of its body, and in the differences of its markings. The dark stripes are more brown than black. The light colour is of a yellowish cream. The stripes are broader and differently arranged (compare Fig. 258 with Fig. 257). A broad stripe runs down the back, and there are no stripes across the top of the croup (Fig. 367). Its legs, below the knees and hocks, from their "flatness," with the back tendons and suspensory ligaments clearly showing, are much more like those of a well-bred horse than are those of the mountain zebra. It further resembles the horse by having a fairly lissom neck and a well-rounded barrel, and in the size of its head and ears. The typical Burchell's zebra
has no dark stripes, or only very slight ones, below the elbows and stifles, on the legs. The Orange River has been generally regarded as its southern limit. Mr. F. C. Selous, the celebrated African sportsman and naturalist, tells me that it “was first discovered by Burchell near the Orange River in Southern Bechuanaland. It is still to be met with in Kama’s country, and along the northern and eastern borders of the Transvaal. In the neighbourhood of the Pungwe River, it exists in very great numbers, herds of hundreds together being common.” It is probably widely distributed throughout Central and Eastern Africa. On account of the fact that this zebra, when in a wild state, possesses immunity from the effects of the bite of the tsetse fly, which is a carrier of death to horses, I strongly advocated, while I was in South Africa, the taming and employment for harness or saddle of these animals in “fly” infected districts. With respect to this subject, Mr. Selous writes to me that: “although Burchell’s zebra, born and brought up in the ‘fly’ country, does not suffer from its bite, it is my opinion that if a young one was caught and brought up in a locality where there was no ‘fly,’ and was then taken into a ‘fly’ infested district, it would die. This, however, is only my opinion.” As the Burchell zebra is comparatively easy to break in, and as it will breed in confinement, there is but little doubt that it will in time become domesticated. If, as is quite possible, it possesses little or no tendency to contract “horse sickness,” it will prove a valuable means of conveyance in South Africa. During one of my horse-breaking performances in 1892, at Pretoria, the capital of the Transvaal, I made a young Burchell zebra, after about an hour’s handling, quiet to carry a rider. In doing this, I did not throw the animal down, nor did I resort to any of the usual “heroic” horse-taming methods. Throughout South Africa, this variety of zebra is wrongly called a quagga.

Chapman’s Zebra (Equus chapmani) appears to be identical with Burchell’s zebra, except that its legs have
Schreiber, Philadelphia.

THE GRÉVY OR SOMALI-LAND ZEBRA.

283

stripes continued down to its pasterns. These leg stripes are not so regularly defined as those of the mountain zebra. As we may meet with specimens having all degrees of striping on the legs, I would submit that the presence or absence of stripes on the limbs is a mere question of individual or local difference, and that the so-called Chapman zebra should not be regarded as a distinct variety.

The Grévy or Somali-land Zebra (Equus gréyi, Fig. 365). This animal, which is found in Shoa and Somali-land, closely resembles the mountain zebra in being striped down to the coronets, and in having the hair of its tail collected as a tuft at the end. It differs, however, in being white underneath the chest and abdomen, and in having white patches on the rear part of the croup at each side of the stripe down the back. Also, there are no transverse stripes on the croup. The stripes are somewhat narrower than those of the mountain zebra, and, in their arrangement, resemble them more nearly than do those of the Burchell zebra, with which it closely agrees in its conformation. The differences in the stripes of these two animals are shown in Figs. 366 and 367.
The Quagga (*Equus quagga*, Fig. 385), forty years ago, was to be found in immense numbers south of the Vaal river in Southern Africa. I have the authority of Mr. F. C. Selous, for saying that it is extinct in a wild state; although it is possible that there may be a specimen or two in some menagerie or other. During a tour four years ago throughout South Africa, I failed to obtain any tidings of the quagga. It was a strong, somewhat heavily built animal, slow of pace for

To face p. 284.
a wild ass, and could have been readily broken to harness or saddle. It stood about the height of the Burchell zebra. Its colour on the shoulders and body was brown. The head and neck were marked alternately with white and dark-brown stripes, like those of the mountain zebra. There were on the shoulders and body some faint stripes, which gradually faded away as they went backwards. The colour was more or less white beneath the chest and belly, on the tail, except at the root, and on the legs below the elbows and stifles. It had a broad stripe down the back. It closely resembled Burchell’s zebra, with the exception of being differently marked, and being more heavily built.

**Points of the Ass.**—The law which I put forward in Chapters I. and XV., with respect to the influence of comparative length of limb on speed and strength, holds as good in the case of the ass, as it does in that of the horse. From it we may justly infer that the onager is the speediest of its class. From personal deductions, which I cannot support by any precise data, I would think that the onager is faster for its size, and under equal conditions, than any kind of wild horse, or, perhaps, than any horse which has not some English racing blood in his veins. As it is not at all probable that this ass will be bred for racing purposes, I need form no conjectures respecting its future on the turf. I have already alluded to the fact of the ass being higher over the croup than at the withers. In the domestic ass, the gaskins and fore arms are, as a rule, very poor; but they are not so, at least to anything like the same extent, in the wild ass. Probably, on account of the ass having fewer loin vertebrae (p. 275) than the horse, it has less tendency to be “slack in the loins.” Compared to the horse, the ass has a very weak tail, and is consequently unable to “carry its flag” in the style usually affected by a spirited horse during movement.
CHAPTER XXIX.*

EVOLUTION OF THE HORSE.

Ancestry of the Horse—Immediate Ancestors of the Horse—Conditions which modified the Form of the Horse—Points of Speed and Strength in the Fossil Horse—The Horse of the Future

Ancestry of the Horse.—It is my intention here, with special reference to conformation, to write about the descent of the horse in such a manner that my remarks may be easily understood by those who possess no acquaintance with fossils or comparative anatomy. Instead of commencing the history of the horse according to the orthodox method, at a period many millions of years ago, I shall begin with him as he now is, and shall try to trace back his lineage to a time sufficiently remote for our requirements. Although we cannot hope to determine the exact sequence of the footsteps of the animals which, in their march of evolution, became gradually changed into the horse; we shall find, on their track, marks left by them, or by their near relatives who accompanied them on their journey, that will guide us in the right direction. As science progresses, so will the intervals between these land-marks become filled in from time to time; though it seems impossible that the position of every footprint can ever be accurately defined.

We learn from the study of geology that living creatures began to inhabit the earth after its crust, which was once in a

* For fuller information on this subject see Professor A. Gaudry's *Enchâînements du Monde Animal*, and Sir William Flower's *The Horse*. 
Fig. 370.—H.H. The Maharaja of Patiala’s Arab Pony, Blitz.

Fig. 371.—Colonel Anderson’s Arab Pony, The Brat.
liquid state, had cooled down, and the action of physical causes, such as wind and water, had commenced to form sedimentary rocks, in which the bones and other remains of existing animals became entombed as fossils. Thus, through countless ages, a history of animal and also of vegetable life has been written in stone by the hand of time. The last leaves of this book lie uppermost, while the first ones repose on fused rock, of which granite is a familiar example. This history is divided by scientific men into the Primary, Secondary, and Tertiary periods, of which the last-mentioned is the only one I shall take into account; as, during it, hoofed animals appeared for the first time on the earth. The tertiary period is divided into the Eocene, Miocene, Pliocene, and Pleistocene periods; the Eocene being the most ancient; and the Pleistocene the one immediately preceding historic times. In searching through the records of the past, an examination of fossil feet is particularly interesting; for we can obtain from it direct and clearly expressed evidence respecting the capacity of movement possessed by the animals which walked on the earth many thousands, if not millions, of years ago.

Before beginning, I may remind my readers that the knee of the horse corresponds to our wrist (p. 27); and his fore fetlock to the row of knuckles nearest to the wrist. Instead of having, as in our hand, five metacarpal bones between the knee and fetlock, he has only one entire bone (the cannon-bone), and two rudimentary (or splint) bones. I may remark that in the hind limb, the bones between the hock and hind fetlock are called metatarsal bones. Each of our five metacarpal and metatarsal bones is furnished with a digit, a synonym for either a toe or a finger; but in the ordinary horse the cannon-bone only is provided with a digit. The bones of each digit (the phalanges) are numbered from above downwards. Thus the long pastern-bone (Fig. 12) is called the first phalanx; the short pastern-bone, the second phalanx; and the pedal or coffin-bone, the third phalanx.

If we examine the bones of the horse’s limbs from, respec-
tively, the knees and hocks downward, we shall notice that although the splint-bones form joints with the knee bones which are immediately above them; their lower ends do not, like that of the cannon-bone, articulate with any other bones. Were a man who knew nothing about the anatomy, working functions, and diseases of any other animal except those of the horse, to criticise the plan according to which the bones below the knees and hocks were constructed; he might justly remark

![Abnormal Left Fore Leg, below the Knee, of Horse (4th real length)](image)

that, for purposes of equine labour, it would have been better if the cannon-bone and two splint bones had been one bone of corresponding size. Such a combination would have rendered the column of bones stronger at that part, and would have obviated the frequent evil effects of sprain to the interosseous ligaments which connect each splint-bone to its cannon-bone. I may here point out that the disease known in veterinary surgery as "splint," is, as a rule, brought on by sprain of this
Fig. 373.—Mr. Dignum’s Arab Pony, Magistrate.

Fig. 374.—American Trotting Stallion, Kremlin (Record, 2.07½).
ligament. If we agree in considering the working of the laws of nature to be perfect, we cannot accept the theory of special creation; but must regard the body of the horse, like that of other animals, to be in a transition state; in that it is constantly, though slowly, accommodating itself to the conditions of life in which it finds itself. While indulging in the present train of thought, the first question which the inquirer after knowledge will probably ask will be: The splint-bones being in a state of transition, what was their previous form and functions, and what conditions have reduced them to their present rudimentary state? I shall now try to suggest answers to these questions.

On rare occasions we find in the horse that one or two of the splint-bones have the character of the cannon-bone, in that they are provided with a more or less perfect pastern and hoof. From time to time there have been well-authenticated instances of horses which were so completely furnished in this respect on their front feet, that, instead of having been shod on only four feet, they carried iron on eight. I need hardly say that the four supplementary shoes were applied merely for exhibition purposes. Such a digit is well shown in Fig. 290, which is a reproduction of a photograph
of the abnormal foot of a pony mare I took in Surrey in 1894. This mare, which was about 132 high, and which was of the light trapper class, suffered no inconvenience in her movements from the presence of the supernumerary digit. At the time I took the photograph, this pony had by her side a smart, healthy foal, whose feet were normal. Fig 372 represents the bones of a colt’s near fore leg that was given by Professor Goubaux to the Veterinary College at Alfort. These new digits are no functionless monstrosities, like a sixth finger or toe which sometimes appears on the hand or foot of man, but are the restorations

FIG 376—(After Gaudry.) HIPPAKION GRACILE (3/4th real height).

of parts once used by the horse’s ancestors. Here we have a good exemplification of the struggle which is constantly going on in the animal body between the tendency to preserve the ancestral type and the effort to adapt itself to its surrounding conditions. If we examine the foot of the pig (Fig. 375), which, like the horse, has hoofs, we shall find that it has two toes upon which it walks, and two supplementary digits which do not touch the ground. As the function makes the organ, we may confidently assert that
Fig. 377.—Kathiawar Mare.

Fig. 378.—Burma Pony.
ancestors of the pig walked on these four toes, two of which, apparently from disuse, have become reduced to their present insignificant size. We may, with equal certainty, affirm that, if the pig remains under its present conditions of life, which, as we all know, do not demand work from its small side toes, these digits will in process of time disappear, and their metacarpal and metatarsal bones will become as rudimentary as the splint-bones of the horse. Even if it were objected that these facts do not warrant us in assuming that the ancestors of the horse had, on each foot, three toes, two of which were more or less rudimentary; we have the still stronger evidence afforded by fossils of horse-like animals.
(Hipparion, Fig. 376), whose feet were in this condition (Figs. 379, 380, 381 and 382). Fig. 383 gives a front view of the horse’s foot. Sir William Flower points out that the European representative (Hipparion gracile) of this fossil family could not have been an ancestor of the horse; for, besides differences in the teeth, it possessed a deep depression in front of the eye, on each side of the face, in which depression was lodged a large tear or scent gland, similar to that found in several kinds of deer.
Fig. 384. — Kiang.

Fig. 385. — Quagga.

To face p. 292.
ANCHITHERIUM.

and antelope. Had the *H. gracile* been the ancestor of the horse, this depression would not have entirely disappeared in the horse. The *H. gracile* does not appear to have left any descendants. It is probable that the immediate ancestors of the horse of to-day (*Equus caballus*) came, in prehistoric times, from America, in which country are to be found the remains

\[\text{Fig. 386 — (After Gaudry), Left front foot of Anchitherium (\textit{4th real length})}\]

\(2m\), second metacarpal bone (inner splint-bone), \(3m\), third metacarpal bone (cannon-bone), \(4m\), fourth metacarpal bone (outer splint-bone), \(p\), first phalanx (long pastern bone), \(p'\), second phalanx (short pastern bone), \(p''\), third phalanx (pedal bone)

of various kinds of fossil horses which resembled our present ones more nearly than did *H. gracile*. The Hipparion flourished in the upper Miocene and lower Pliocene ages, and was from 13 to 14 hands high.

The Hipparion was preceded in the Miocene period by a somewhat similar, three-toed animal, the Anchitherium, which was about 10 hands high. We may see from Fig. 386 that its side toes were longer than those of its successor. The Russian palæontologist, Kowalevsky, points out that the bones below the fetlock in the Anchitherium were not so firmly united together as they were in the Hipparion, and
still less so than in the horse; and, consequently, that there must have been a certain amount of lateral play in them. The length, also, of the side digits would lead us to form the opinion that this animal walked on three toes.

The majority of palæontologists, I believe, consider that the Hipparion used only one toe of each foot in progression. Against this opinion I may advance the fact, not very generally known, that some horses, especially high-caste Arabs, have such a naturally large amount of "play" in the fetlock and pastern joints of the fore legs, that during the fast gallop the fetlock pad (p. 197) is liable to come down on the

![Figure 387](image1)

![Figure 388](image2)

ground and get bruised. The ergot, which is in the centre of this pad, is evidently, as pointed out by Sir William Flower, the rudiment of a structure (like the pad of a dog's or cat's foot) that acted as a buffer to the fetlock at the time when the horse was a digitigrade animal, namely, one which walks on its digits, and not as the horse now does, in unguligrade fashion, only on their tips. In all horses which have free action, the fetlock descends a good deal in the gallop (Fig. 128). Hence, I am inclined to think that the Hipparion, whose immediate ancestors were digitigrade animals, used the second and fourth digits, at least of its fore feet, to some extent at fast paces; if not in slow movement.

Still earlier, we find in the middle Eocene age the
Paloplotherium, which resembled the Anchitherium and Hipparion in its feet (Fig. 387); and the horse tribe, generally, in its teeth.* Its principal digit was much weaker than that of its successors. The foot shown in Fig. 387 is that of a small variety of Paloplotherium. Among the Eocene deposits in America is found the Orohippus agilis † (Fig. 388), which, as the name given to it by Professor Marsh implies, may be taken as the limit to which we can fairly trace the horse in his character of a one-toed animal. Going further back in the Eocene period, we meet with the Hyracotherium (Fig. 389), which had three toes on its hind feet and four toes on its front feet, and which had hoofs on all of them. It was about 15 inches high, and was closely akin to the tapir, which has maintained its peculiarities of conformation, up to the present day, almost without change, during that vast period of time.

* The teeth of the Paloplotherium have a plentiful supply of crīstā pātrōsa (cement), and thus resemble those of the horse. I may explain that the cement is the outer layer of the teeth. In youth, it forms a thin covering to the enamel on the outside; and a thick one in the depressions which all the teeth, with the exception of the tushes, have on their crowns. The cement becomes quickly stained by the action of the food and gives the "mark" in the teeth its characteristic dark appearance. The front teeth of the horse become white with age from the wearing away of the cement.

† Ὄφος, limit; ὅρης, horse.
Although the Hyracotherium had four toes on its front feet, it may be considered to have been an odd-toed animal; for one of these digits was off the ground, and was consequently functionless.

The foot of the rhinoceros (Fig. 390) shows a marked tendency to become one-toed. Being three-toed on its fore, as well as on its hind feet, it belongs to a less ancient type than the tapir. The Acerotherium (Fig. 391) was a probable ancestor of the rhinoceros, if not of the horse. The Brontotherium, which has been found in the Miocene of Colorado, had, like the tapir, four digits on its front feet, and three on its hind ones (Figs. 392 and 393).
Proceeding still further down in our search, we find in the early Eocene the *Phenacodus primavus*, which is supposed to have been the ancestor, or one of the very early ancestors, of all hoofed animals. Fig 394 shows how it appears in a fossil condition. It was about twenty-one inches high. From the form of the third phalanx of its digits, we may conclude that each of them carried a hoof. We may also see that each of its digits had three phalanges. As I am considering the genealogy only of hoof-bearing animals, I shall not go further back than the *Phenacodus*. Having now arrived at an animal with five toes, I may point out that in no case do the digits of any normal mammal (an animal which suckles its young) exceed that number. The digits, I may remark, are numbered from within, outwards. Thus, the thumb on our hand is termed the first digit, the little finger, the fifth digit. Among the ancestors of the horse, the first digit was the first to disappear; and after it, the fifth digit. In the Hyracotherium, the first digit has gone from all four feet. The fifth has vanished from the hind ones, and has begun the process of doing so in the front feet. The Orohippus has also lost its first digit. The Anchitherium (like the rhinoceros)
appears as a true three-toed mammal; having lost its first and fifth digits. In the *Hipparion gracile*, the second and fourth digits have begun to disappear; and have done so completely in the horse of the present day, whose ancestors, from the foregoing considerations, are classed among odd-toed animals (*Perissodactyla*). We must further observe that, from the Phenacodus to the horse, as we now know him, the third digit has remained the principal one of both fore and hind limbs. It is instructive to note that the phalanges and digits of the hind limb have a greater tendency to decrease in number than those of the fore leg. As the fore foot is nearer to the head than the hind foot, its functions are more various, and its digits are less liable to become affected by disuse. In man, we find that the toes are smaller than the fingers; and that, in many cases, the little toe has lost its third phalanx; although the little finger still retains that bone. In the case of the re-appearance of the second (as in Fig. 290) and fourth digits in the horse, the fore legs are far more frequently supplemented in this way, than the hind ones.
Immediate Ancestors of the Horse.—The type of horse immediately preceding the present one, is a subject which I approach with a great deal of diffidence; as I have not had an opportunity of studying it carefully, much as I would have wished to have done so. Darwin, very justly as it seems to me, points to the probability that all the existing races of horses have descended from “a single dun-coloured, more or less striped primitive stock, to which our horses occasionally revert.” This primitive stock, I would conjecture, closely resembled the quagga or Burchell’s zebra. The not uncommon appearance in horses of dark stripes on the fore arms, and a dark stripe along the back and across the shoulders, seems to be cases of reversion to the likeness of an ancestor, especially as these markings, when they do occur, show much clearer in early youth than when the animal grows older. Not alone in this respect does the horse take on the markings of the ass; but his coat not infrequently assumes a near approach to the colour of the ass, with white under the belly, insides of the legs, etc. The ass, on the contrary, never clothes himself in the bays, chestnuts, roans and greys which are greatly affected by the horse; and is practically free from the irregular markings so freely indulged in by his relative. “Stars,” “blazes,” “reaches,” “snips,” “stockings,” and coats, piebald and skewbald, can hardly be the unbiassed result of domestication; for the ass appears to have been the companion of man even longer than the horse, and he shows little or no tendency to adopt such motley wear. The apparently functionless false nostril of the horse is of lesser depth than that of the ass, and may be expected to disappear in the course of ages. I would therefore infer that the immediate ancestor of the horse, as we know him, was a more or less striped ass. From the drawings made on pieces of bone and horn by the cave men of Southern France, it would seem that the horse of Western Europe, say, ten thousand years ago, was a small, rough, thick-set animal, rather like the Mongolian pony. The instinct this and other horses have of scraping away with their fore feet snow when it covers the ground, so as to get at the underlying grass, would,
as Darwin suggests, point to the probability that our horses originally came from a country in which there were severe winters. It would be interesting to know if this instinct, which no doubt is possessed by the kiang, is retained by the onager, the Abyssinian wild ass, and the eastern horse. The horses of the present day may be divided into two, more or less, distinct types; the one, thick-set and "coarse," like the Mongolian pony; the other of comparatively slight build and smart appearance, like the Arab or Indian pony (Fig. 377). I would refer the aboriginal horses of Western Europe and the various cart strains to the first division. Our saddle horses and trappers are, as we all know, a judicious blend of English and Eastern blood. The differences which exist among the various breeds of horses in the world, are evidently due to the effects of climate, selection, and stable management.

From the remarks made on page 276, with respect to the presence of thickened skin in the horse and ass, we might conclude that these two animals are descended from a thick-skinned ancestor, akin perhaps to the rhinoceros, whose foot (Fig. 390) shows a marked tendency to become one-toed. It is almost needless to say that the rifle of the sportsman will, in the near future, put a summary stop to this process of evolution in the case of this horned pachyderm. The fact of the ass possessing a larger amount of thick skin than the horse, also seems to prove that his type is the more ancient one of the two. Judging by the general conformation, especially as regards the comparative size of head, Burchell's zebra appears to be the nearest akin, among asses, to the horse; and the mountain zebra, the furthest removed. The recent extinct quagga more closely resembled the horse, than does Burchell's zebra.

**Conditions which Modified the Form of the Horse.**
—The conditions which have produced an animal (the horse) with a single toe to each of its feet, from ancestors with five toes, have been, apparently, those of soil, combined with a
tendency to place the weight of the limb more on one particular digit than on any other digit. The fact that the feet of the tapir have undergone, practically, no modification for several millions of years, proves that his conditions of life at the present day are nearly the same as they were when the ancestors of the horse, like those of the tapir, had four hoofs on each front foot, and three on each hind one. Feet like these, which, under the influence of pressure, had the faculty of spreading out, were admirably suited for going through soft ground similar to that over which the tapir still roams in a wild state; for the increase of the area of support thus offered by the feet, was a direct help in preventing the animal from sinking too deeply in the mud over which he travelled. It is evident that this lateral play of the digits entailed loss of speed for progression on hard ground, on account of expenditure of muscular power required to restore them to their normal state, and from increased friction. The less lateral play the digits would have, the faster would the
animal be able to travel over hard ground. For instance, the wild pig, whose feet (Fig. 375) spread out a good deal more than those of the steinbok (Fig. 395), is much better through “dirt” (to use a racing and hunting expression) than this speedy South African antelope, but is far inferior to him in a gallop over hard ground. We may, therefore, infer that the decrease in the number of the digits of the horse’s foot has been due to residence during thousands, if not millions, of generations on dry soil. With the loss of lateral play in the foot, there has been a consequent increase of speed, which was necessary for protection against the attacks of carnivorous animals, like the cheetah (Fig. 3) and wolf, whose conformation was unsuited for predatory operations in the morasses which had afforded an asylum for ancestors of the horse.

Points of Speed and Strength in the Fossil Horse.
—At the outset of this investigation, I am met with the pertinent question: what is a horse? My natural reply to this will be that the horse is an animal which has only one toe to each of its legs. I might also add, for the benefit of those of my readers who are interested in comparative anatomy, that his teeth are plentifully supplied with *crusta petrosa* (p. 295), and that the pulley-like processes on his astragalus are directed forward and outward (p. 58). The fact of unity of digit—a peculiarity which distinguishes the horse from all other mammals—will probably suffice for ordinary inquirers. Taking this test, we cannot with propriety apply the term horse to animals further back in equine descent than the Anchitherium. The Phenacodus resembles a carnivorous animal (a Dandy Dinmont or otter hound) more than he does one of the horse tribe. His great length of humerus must have given him considerable power in raising the fore hand by the play of the shoulder and elbow joints, the diminution of which play is compensated for in the horse by the action of the fetlock joint. His hocks and knees, like those of the dog and cat, were “well let down.”
He might have had a fair "turn of speed" for a short distance, but he was too long in the body to have been a stayer. There is no doubt that the ancestors of the horse were of very slow pace at the time when they were identical with, or nearly akin to, the Paloplotherium and the Hyracotherium, animals which were not far removed from the rhinoceros and tapir. With the tendency to the gradual adoption of the one-toed method of progression, there was an evident increase of speed. By examining Figs. 379 to 383 and 386, we may see that the length of the bones below the fetlock, compared to that of the cannon-bone, was greater in the Hipparion than in the Anchitherium; and in the horse, than in the Hipparion: length of pastern, as we have seen on p. 200, being directly conducive to speed. Taking the converse of this argument, which we may fairly do from our present knowledge of palaeontology, we may assume that this increase in the comparative length of the bones below the fetlock is a sound proof that this kind of conformation is conducive to speed.

Although, as regards the number of toes, the horse's foot is better suited than that of any other animal for the development of a high rate of speed; the fact remains that the four-toed cheetah (Fig. 3), hare, wild dog, and wolf, and the two-toed black buck (Fig. 1) are comparatively, for their size, if not actually, faster than any wild horse or ass. Here we have an instance of the complex nature of physical faculties, which, like speed, are not made up of one component, but of many. In the cat, dog and hare, the muscles of progression are of much greater comparative length than those of the horse; as we may judge by the way the hocks and knees are "let down." Although these joints in the antelope are "high off the ground," the extreme length of his limbs compensates him for this disadvantage, as well as that of having two toes on each foot. In the case of the ancestors of this fleet ruminant, the tendency to place weight both on the third and fourth toe was so evenly distributed on these two digits, that the balance between them has remained practically un-
EVOLUTION OF THE HORSE.

disturbed for ages, and under modifying conditions which have nearly doubled the comparative length of the limbs.

Like the horses of the present day, the members of the *Hipparion gracile* tribe differed a good deal among each other as regards conformation; as we may see by the fact that the cannon-bones of some are very much thicker than those of others.

**The Horse of the Future.**—The bones of the limbs, as we have seen, are gradually assuming the character of a single column, and are increasing the rigidity of their connections between the joints necessary for locomotion. We may observe a tendency to bony union between the splint bones and their cannon-bones, and between the lower row of the small bones of the hock and knee, and their respective metatarsal and metacarpal bones. Thus we find that comparatively harmless forms of "simple" splint and "low" spavin are increasingly common among young horses subjected to civilised conditions. They will, as suggested by Mr. H. G. Rogers, gradually lose their morbid character, and will become normal processes of development. Agreeably to this, we may note that such splints and spavins are less liable to injuriously affect the usefulness of a thoroughbred than of, for instance, a Mongolian pony or a South American broncho. As ages roll on, the splint bones will disappear, and *pari passu*, the small bones of the knee and hock which rest on them. The increasing prevalence of "side-bones" among heavy cart-horses seems to justify the idea that the Shires and Clydesdales of the near future will have no lateral cartilages. Among other changes, the bones of the sternum will in time become joined together, and anchylosis will take place between the pelvis and sacrum. The racer will become comparatively longer in the legs and neck, stronger in the loins, rounder in the barrel and better ribbed up than he now is; and the draught animal will become shorter in the limbs, and more massive in muscle. Both will increase in height and docility.
CHAPTER XXX.

PHOTOGRAPHING HORSES.

Photography is a very useful aid for the acquisition of a knowledge of conformation; for it enables us to place on record exact results unobtainable by other means. This is a truth which is too evident to need support by argument.

Photographs are taken of a horse with the object of obtaining a picture, a portrait, a combination of the two, or a likeness of the animal by which his "points" may be best seen and compared, with the greatest exactness, to those of other horses. When a picture is the end in view, the pose will have to be subordinated to artistic requirements. If a portrait, the position should be that which will convey to the spectator the best possible idea of the general look of the animal. This will usually be obtained when his body is in profile, and the head and neck carried in the manner most characteristic of the horse in question. My experience is that horses in photographs look better when the head is turned a little towards the observer (Figs. 236, 256, 344 and 370) or is directed straight to the front (Fig. 322), than when it is turned even slightly away (Fig. 255). When, however, the photograph is required as a more or less exact record of the horse's "make and shape," he should be in as nearly perfect profile as practicable: just as if he were posed for the inspection of an intending buyer.

In order to preserve harmony in the graceful curves of the upper line of the body, the horse, to look his best, should have his ears pricked forward, his head carried high, and, if possible, he should not have his tail tucked in between
his legs. When standing still, he will look to most advantage when the fore leg of the observer's side is more advanced than the other, and when its hind leg is more drawn back than the other hind leg (Figs. 324 and 370). Unless the background be a specially prepared one, the horse should be well away from it, and it should be out of focus, so that he may stand out in bold relief. As a rule, the animal, even when he is a grey or white, should be placed, more or less, against the sky. If possible, the horse should not be put, as is frequently done, close against a building, the lines of which would prevent the eye from following the contours of the animal. My readers will see many illustrations of these points in this book. I find that horses look more animated and hold themselves better, away from their stables, than near them; and especially when they are in an open plain.
CHAPTER XXXI.

PROPORTIONS OF THE HORSE.

BOURGELAT, Merche, Duhousset, Goubaux, Barrier, and other writers on Conformation have laid down certain proportions for an ideal horse, which, unfortunately; does not exist as a distinctive type. Failing to draw sufficient attention to the great difference of shape between horses of speed and those of strength, the comparisons which they have instituted between the dimensions of the limbs and those of the head and body are wholly arbitrary. I need hardly remind my readers that, speaking generally, although the respective proportions of the head and body are practically the same in all classes of horses, the length of the neck and limbs varies according to the work for which the muscles of these parts are best suited. Hence the only proportions of the horse which are fixed within narrow limits are those of the head and body. We may sum up the most evident ones as follows:

Proportions Common to all Classes of Horses.

The measurements here given have reference to Fig. 396.

(1) Length of body \((a \ b) = 2\frac{1}{2} \) to \(2\frac{2}{3}\) times length of head \((k \ l)\).
(2) Height at withers \((c \ d) = \) height at croup \((f \ g)\).
(3) Length of head \((k \ l) = \) depth of body at lowest part of back \((h \ i)\).
(4) Length of head \( = \) distance of "swell" of muscle at posterior angle of shoulder-blade to point of hip \((s \ t)\).
(5) Distance \((k \ p)\) of top of head to corner of mouth \( = \) distance from point of hip to point of buttock \((t \ u)\).
(6) Width of head \((m \ n) = \frac{1}{2} \) length of head \((k \ l)\).

That careful observer, Colonel Duhousset, states that

(7) Length of head \( = \) distance of point of shoulder to top of withers.
As this proportion must necessarily vary according to the length and position of the shoulder-blade, I refrain from applying it to all classes.

The following proportions are approximately correct for all horses, except those of the heavy cart type, whose necks are particularly massive, as in Fig. 334:

(8) Width of head \((m\, n)\) = width of upper part of neck \((n\, o)\).

(9) Distance \((k\, p)\) of top of head to corner of mouth = thickness of base of neck \((q\, r)\).

Any attempt—as has frequently been made—to formulate proportions of length between the limbs and body of what might be called an “ordinary horse,” would be merely begging the question by constructing an ideal animal to conform to one’s own theories; instead of, as one ought to do, supporting one’s hypotheses on the firm basis of fact. As the comparative length of limb varies according to the class of horse; we find (Chapter XV.), taking the two
extreme types, that the legs of the heavy cart-horse are far shorter than those of the racer (compare Fig. 334 with Fig. 322). Thus, in the cart-horse, the length of the body and its depth at the withers are, respectively, several inches more than the height, and the distance of the brisket from the ground. The racer, on the contrary, is inclined to be shorter than he is high, and measures much less from the withers to brisket than from brisket to ground.

As the result of my own observations I may add the following proportions for thoroughbreds only:—

(10) Height at withers \((c d)\) = length of body \((a b)\), or a little (say, up to 4 inches) more.

(11) Depth at withers \((c e)\) = distance of "girth place" to lower part of fetlock in a three-year-old, or to centre of pastern in an "aged" horse.

Beyond repeating (p. 136) that the muscles of the neck should be proportionate in length to those of the limbs, I can offer no useful hint as regards the comparative length of the neck; for the only measurement which can be readily taken of it, namely, that from the withers to the top of the head, greatly alters in length, on account of the elasticity of the connecting ligament (p. 28), according to the position in which the head is held. We must here remember that this suspensory ligament of the head and neck is immediately underneath the crest, and that the vertebrae of the neck (Fig. 12) do not follow this line.
CHAPTER XXXII.

THE PAINTER'S HORSE

Horses have been treated by painters, and also by sculptors, in a very unhandsome way, and especially by English so-

called artists who continue to perpetuate the conventional or stencil-plate animal in a style long since forsaken by continental draughtsmen. There are, of course, several brilliant exceptions. The most usual faults of conformation to be seen in horse pictures, are absurdly small heads and extravagantly long hind-quarters, from point of hip to point of buttock, as we may see in Figs. 397 and 398. The former is a sketch of an equestrian portrait, by the French

---

Fig 397 — (Copied from DuHousset) Louis XV.
artist Parrocel, of Louis XV. in his youth. The latter is from Beauties and Defects in the Figure of the Horse, by H. Alken, who published it seventy years ago, and who described the subject of his work as follows: "The animal from which this drawing was made, is accounted one of the finest figures in England." He must have had some misgivings about the dimensions of the head and neck, for he takes care to add that: "A small head and neck in a horse are considered a great beauty, and in the original of this drawing, I think they are the least I ever saw in proportion to the body." All the saddle-horses of some English artists, among whom was that unrivalled caricaturist, Mr. John Leech, have a remarkably "good place for the collar" on their shoulders. "The old masters" drew horses very incorrectly; and yet we find in the bas-reliefs of the Parthenon done over two thousand years ago, horses depicted with a near approach to truth both in form and action (Fig.
Meissonier drew horses with marvellous correctness, as we may see in his "Napoléon 1er" (Fig. 400), and in "1814" (Fig. 401). He was not alone attentive to truth in the proportions of his horses; but was also singularly happy in catching the character of different classes and breeds: for instance, compare (leaving out the question of attitude) the Arab horse in Fig. 400 with that in Fig. 281. Some represent the walk by the action of the trot. Even Géricault gave the movements of the amble for those of the walk, as Duhouset shows us in Le Cheval. A well-known English artist drew a picture of Napoleon's charger, Marengo (Fig. 407), balancing himself on a fore and hind leg of the same side! Artists of the present time have no excuse for similar lapses into error; for they have the results of the researches of Marey, Muybridge, Anschütz, and other photographers to guide them. Photography proves that the walk (Figs. 402, 403, 404, and some of the series, Figs. 96 to 106), trot (Figs. 69, 208 and 405),
canter (choose from series, Figs. 123 to 132), gallop (Fig. 406), and leap (Figs. 195 to 199, 200, 204, 206 and 409) can be drawn artistically and truthfully at the same time. A combination of these two conditions is harder to find in the canter, and especially in the gallop, than in the other movements. The difficulty, here, lies in the nature of the action rather than in the speed of the pace; for the eye can, for instance, follow the order in which the limbs work far more easily in the fastest trot or amble than in the slowest walk. Here we come to the noteworthy truth that the eye will seldom recognise as true in Art what it has not actually seen in Nature. The distance from which we usually look at the movements of a horse's legs in the canter or gallop is usually too close to permit us to take in all four together at the same moment. Hence, when
critically regarding the action in either of these two paces, we generally content ourselves with studying that of the fore pair, and, subsequently, that of the hind pair; or vice versa. In such a case, therefore, whichever pair be focussed sharply on the retinae of our eyes, the other pair will of necessity be blurred. Consequently, if both pairs of limbs be depicted sharply in the canter or gallop, the chances are that the idea of motion will not be conveyed to the spectator. For this reason, the painter who is trying to give the "feeling" of motion to a horse he is drawing at either of these paces, will do well to blur (by means of dust, snow, etc.) or to hide (by a bush or grass, for instance) one pair, if he desires to make the other pair sharp. I can see no error of technique in giving indistinctness of outline to the limbs themselves. A painter who exhibited, in the Royal Academy or Salon, a picture representing a horse running away with a carriage,

Fig. 405.—Ganymede Trotting.

Fig. 406.—Riding a Gallop.

To face p. 314.
would most probably incur no rebuke from the art critics for blurring all the spokes of the wheels, and drawing all the legs and feet of the animal sharp. And yet those of us who know anything of the laws of motion, must be aware that, in such a case, any one of the horse's feet which is going forward, must be passing far faster through space, than the more or less perpendicular spokes which are revolving through the lower half of their circle. The blurred appearance of the near fore foot of the horse in Fig. 406, shows that that foot was rapidly going forward at the moment the photograph was taken. The fact of the horse pulling his rider out of the saddle, gives the idea of movement, which Fig. 309 fails to convey.

At paces in which there is a moment of suspension, the idea of motion, will, as a rule, be best conveyed by drawing the horse with his feet off the ground. On account of violating this principle, old time painters, who represented the horse in the gallop with both hind feet on the ground, failed to give the idea of movement; although, as it happened, the attitude they adopted was not far from true (Fig. 136). The later method of showing the racer at full speed, suspended in the air, with his fore legs stretched out in front and his hind limbs extended to the rear, was absolutely incorrect.
THE PAINTER'S HORSE.

as well as utterly impossible; and yet it conveyed the feeling of motion better than that practised by the earlier horse painters. It is manifest that a pictorial attitude which we know to be incorrect, will look unnatural to us. Consequently, the more general knowledge becomes, the more difficult will it be for a painter who tries to draw horses in motion, to satisfy the artistic requirements of his public. Hence, pictures

![Fig. 408.—Horse Leaping, by Alken.](image)

of galloping horses appearing to claw the ground, as the fore feet come down with the knees and fetlocks well bent, or committing equally absurd eccentricities, will, to any one who has studied the paces of the horse, look simply ridiculous, no matter how meritorious the painting may be in other respects. Barroil (L'Art Équestre) justly remarks that the fact that the domain of the painter is what one sees and not what really takes place, is no proof that one sees attitudes which do not exist. "It is, however, by virtue of this theory,
set up as an axiom, that many artists represent, in their works, horses in attitudes which they have never assumed, and which they could not assume."

A common form of conventional leap appears to have been taken from Alken's drawing (Fig. 408). It is neither correct, nor does it give—at least, to a horseman—the idea of what is intended to be represented. A horse in the act of landing is often represented with its fore feet so far to the front that, when they will come to the ground, it could not possibly raise its fore hand, and a fall would be the inevitable result. Fig. 409 gives a correct rendering of the action at this moment; the idea of movement being greatly heightened by the happy position of the horses, which follow one after the other. A method of recent date is to give the animal, just before landing, the appearance of being afraid to face his bit. Consequently, although the position may be true, it will look constrained and awkward to the eye of a cross-country expert, which is a rôle that such artists are evidently unqualified to assume. I need hardly say that the more an artist knows, the better will he paint.

BIBLIOGRAPHY.

The following are the chief books which have been written on the Conformation of the Horse, and on Equine Locomotion:

Alix, Eugène.— *Le Cheval*, 1886.
Barroil, Étienne.— *L'Art Équestre*, 1st Part, 1887.
Borelli.— *De Motu Animalium*, 1680.
Bourgelat.— *De la Conformation Extérieur du Cheval*, 1808.
Carson, J. C. L.— *The Form of the Horse*, 1859.
Duhousset, Colonel.— *Le Cheval*, 1881.
Fearnley, W.— *Lessons in Horse Judging*, 1879.
Gayot, Eugène.— *Achat du Cheval*, 1862.
Goubaux and Barrier.— *The Exterior of the Horse*. Translated and Edited by S. J. Harger, V.M.D. 1892.
Güntner's— *Beurtheilungskhre des Pferdes*, 1889.
Hofman, L.— *Das Exterieur des Pferdes*, 1887.
Lecoq, F.— *Exterieur du Cheval*, 1843.
Marey, Professor.— *La Machine Animale*, 1873.
Mercère.— *Nouveau traité des formes extérieures du Cheval*, 1868.
Montigny, Comte de.— *Comment il faut choisir un Cheval*, 1885.
Morris, Général.— *Essai sur l'Exterieur du Cheval*.
Müller.— *Lehre vom Exterieur des Pferdes*, 1884.
Muybridge, E.— *Animal Locomotion*, 1887.
Percivall, W.— *Lectures on the Form and Action of the Horse*, 1850.
Richard, du Cantal.— *Étude du Cheval*.
Roloff.— *Beurtheilungskhre der Pferdes*, 1870.

Besides the books just enumerated, many useful remarks on the form and movements of the horse may be found in the writings of Henri Bouley, "Stonehenge," Youatt, Lupton, Lenoble du Theil, Barroil, Raabe, Colin, and Ellenberger; in chapters on the Exterior of the Horse, in Schwarmzecker's *Pferdsucht*, 1879; and in the *Handbuch der Pferdekunde*, by Born and Möller, 3rd ed., 1890.

MDCCCLXXVII.
The SECOND EDITION of Captain Hayes' Important Work on

POINTS OF THE HORSE.

A FAMILIAR TREATISE ON EQUINE CONFORMATION.

By M. HORACE HAYES, F.R.C.V.S.

(Late Captain "The Buffs.")

The present Edition has been thoroughly revised and contains numerous additions, including specially written Chapters on the Breeds of English and Foreign Horses, with over Two Hundred beautiful Illustrations reproduced from Photographs, the larger number of which were taken by the Author and have never before been published.

Super-Royal 8vo., Cloth, Gilt Top, Price 34/-.

Also a Large Paper Edition, strictly limited to One Hundred and Fifty Copies for England and America, each numbered and Signed by the Author, printed by Messrs. William Clowes & Sons, Ltd., on paper specially manufactured for this Edition. [Nearly all Subscribed.]

Demy 4to., handsomely bound in best Buckram Binding, top edges gilt, uncut, price 63/- net.

"An elaborate and instructive compendium of sound knowledge on a subject of great moment to all owners of horses, by a writer of established authority on all matters connected with the horse."—Times.

"We hail the advent of a work on the subject by such a past master of the arts hippic as Captain Horace Hayes, late of 'The Buffs,' and a Fellow of the Royal College of Veterinary Surgeons, the author of several of the most simple and thoroughly instructive treatises upon riding, breaking, and veterinary treatment of the horse."—Land and Water.

"There is not a page in the book that does not display knowledge, and those who desire to become familiar with the character of the horse will find the work invaluable. It is scientific in its method, and practical in its purpose."—Army and Navy Gazette.

"A soldier, a certificated veterinarian, a traveller, and a successful rider, the author is well qualified to treat on all that pertains to the subject before us."—Nature.

"This is another of Captain Hayes' good books on the horse, and to say it is the best would not be going far out of the way of truth. It is a luxurious book, well got up, well and clearly printed in large readable type, and profusely illustrated."—Saturday Review.

"A volume that must be regarded as a standard work on the subject. It is well done. No point is left unexplained; no quality in a type unnoticed."—Pall Mall Budget.

"To those who are delectors of availing themselves of the knowledge of a writer who has been used to horses all his life, the book may be cordially recommended."—Field.

"No book like this has hitherto appeared in English, or any other language. For giving us such a beautiful, interesting and instructive book, the members of the veterinary profession, horsemen and horse owners, as well as delineators of the horse, in every English-speaking country must acknowledge themselves deeply indebted to Captain Hayes."—Veterinary Journal.
VETERINARY NOTES...

...FOR HORSE-OWNERS.

By Capt. M. H. HAYES, F.R.C.V.S.

This Edition is revised throughout, considerably enlarged, and incorporates the substance of the Author's "Soundness and Age of Horses."

The chief new matter in this edition is—articles on Contracted Heels, Donkey's Foot Disease, Forging or Clicking, Rheumatic Joint Disease, Abscess, Dislocation of the Shoulder Joint, Inflammation of the Mouth and Tongue, Flatulent Distention of the Stomach, Twisting of the Intestines, Relapsing Fever, Cape Horse Sickness, Horse Syphilis, Rabies, Megrima, Staggers, Epilepsy, Sunstroke, Poisoning, Castration by the Ecraseur, and Mechanism of the Foot (in Chapter on Shoeing).

"It is a thoroughly practical work and may be recommended with confidence."—The Field.

"Is a valuable addition to our stable literature, and the illustrations, tolerably numerous, are excellent beyond the reach of criticism."—Saturday Review.

"Leaves nothing to be desired on the score of lucidity and comprehensiveness."—Veterinary Journal.

"A necessary guide for horse-owners, especially those who are far removed from immediate professional assistance."—The Journal.

"Of the many popular veterinary books which have come under our notice, this is certainly one of the most scientific and reliable. If some painstaking student would give us works of equal merit to this on the diseases of the other domestic animals, we should possess a very complete veterinary library in a very small compass."—Field.

"The present edition is nearly double the size of the first one, and the additional articles are well and clearly written, and much increase the value of the work. We do not think that horse owners in general are likely to find a more reliable and useful book for guidance in an emergency."—Field.

"Simplicity is one of the most commendable features in the book. What Captain Hayes has to say he says in plain terms, and the book is a very useful one for everybody who is concerned with horses."—Illustrated Sporting and Dramatic News.

"The usefulness of the manual is testified to by its popularity, and each edition has given evidence of increasing care on the part of the author to render it more complete and trustworthy as a book of reference for amateurs."—The Lancet.

THE HORSEWOMAN.

By MRS. HAYES. Edited by Capt. M. H. HAYES.

A PRACTICAL GUIDE TO SIDE-SADDLE RIDING.

With Numerous Illustrations and Drawings from Photographs by Oswald Brown.

"A large amount of sound, practical instruction, very judiciously and pleasantly imparted."—The Times.

"This is the first occasion on which a practical horseman and a practical horsewoman have collaborated in bringing out a book on riding for ladies. The result is in every way satisfactory, and, no matter how well a lady may ride, she will gain much valuable information from the perusal of 'The Horsemansman.' The book is happily free from self-laudatory passages."—The Field.

"A most useful and practical book on side-saddle riding, which may be read with real interest by all lady riders."—The Queen.

"Mrs. Hayes is perhaps the best authority in these countries on everything connected with horsemanship for ladies."—Freeman's Journal (Dublin).

"With a very strong recommendation of this book as far and away the best guide to side-saddle riding that we have seen."—Saturday Review.
Illustrated Horse-Breaking

By Capt. M. H. HAYES, F.R.C.V.S.

This Edition has been entirely re-written; the amount of the letterpress more than doubled; and 75 reproductions of Photographs have been added.

"It is a characteristic of all Captain Hayes' books on horses that they are eminently practical, and the present one is no exception to the rule. A work which is entitled to high praise as being far and away the best reasoned-out one on breaking under a new system we have seen."—The Field.

"The work is eminently practical and readable."—Veterinary Journal.

TRAINING

AND

HORSE MANAGEMENT in INDIA

By Capt. M. H. HAYES, F.R.C.V.S.

"An useful guide in regard to horses anywhere. Concise, practical, and portable."—Saturday Review.

"We entertain a very high opinion of Captain Hayes' book on 'Horse Training and Management in India,' and are of opinion that no better guide could be placed in the hands of either amateur horseman or veterinary surgeon newly arrived in that important division of our empire."—Veterinary Journal.

"We have always been able to commend Captain Hayes' books as being essentially practical and written in understandable language. As trainer, owner, and rider of horses on the flat and over country, the author has had a wide experience, and when to this is added competent veterinary knowledge, it is clear that Captain Hayes is entitled to attention when he speaks."—The Field.
RIDING:
On the Flat and Across Country.
A GUIDE TO PRACTICAL HORSEMANSHIP.

By Capt. M. H. HAYES, F.R.C.V.S.

Eighty Illustrations by Oswald Brown, Sturgess, and Stanley Berkeley.

"Captain Hayes' hints and instructions are useful aids, even to experienced riders, while for those less accustomed to the saddle his instructions are simply invaluable."—The Times.

"To possess knowledge and to succeed in imparting it, are two different things; but Captain Hayes is not only a master of his subject, but he knows how to aid others in gaining such a mastery as may be obtained by the study of a book."—The Standard.

"We are not in the least surprised that a third edition of this useful and eminently practical book should be called for. On former occasions we were able to speak of it in terms of commendation, and this edition is worthy of equal praise."—The Field.

"We heartily commend it to our readers."—Sporting Times.

"Is as practical as Captain Horace Hayes' 'Veterinary Notes' and 'Guide to Horse Management in India.' Greater praise than this it is impossible to give."—The Graphic.

AMONG MEN AND HORSES.

By Capt. M. H. HAYES, F.R.C.V.S.

"To sportsmen, and especially to horse-lovers, it should prove irresistibly interesting."—The Globe.

"A most interesting book."—The Spectator.

"All Irishmen, except those in Parliament, are supposed to have a keen sense of humour, and Captain Hayes admirably illustrates this national characteristic—his stories are always funny and mostly new."—The Saturday Review.
MODERN POLO.

A Practical Guide to the Science of the Game, Training of Ponies, Rules, etc.

By Mr. E. D. MILLER, Late 17th Lancers.

Edited by Capt. M. H. HAYES, F.R.C.V.S.

A practical and exhaustive description of the science of the game, duties of players, selection, breaking, training, and management of ponies, various breeds of ponies in all parts of the world. Polo in India; Hurlingham, Indian, and American Rules, etc. Beautifully illustrated with sixty-four reproductions of Photographs showing the various “points” of the game, famous ponies, players, etc.

CONTENTS.—Chapter I. First Steps at Polo.—Chapter II. Theory and Practice of Polo.—Chapter III. Polo Appliances.—Chapter IV. Choosing a Polo Pony.—Chapter V. Training the Polo Pony.—Chapter VI. Polo Pony Gear.—Chapter VII. Polo Pony Management.—Chapter VIII. Various Breeds of Polo Ponies.—Chapter IX. Polo in India.—Chapter X. Polo Pony Breeding.—Chapter XI. Veterinary Advice to Polo Players.—Appendix. Tournaments, Laws and Bye-Laws, etc.

"Both in the matter of polo playing and in that of choosing or breeding polo ponies, the volume is a certain authority."—Times.

"Modern Polo," written by E. D. Miller and edited by Capt. M. H. Hayes, will assuredly become the authoritative work concerning the game, which is rapidly growing in favour in this country. It is clear and bright in style, and it is provided with numerous illustrations from photographs."—Black and White.

"Mr. Miller's is by no means the only work upon the Game of Polo, but it is, at least, the most complete and comprehensive work upon this subject that has yet been issued. It has had the benefit, too, of the editorship of Capt. M. H. Hayes, one of the best authorities of the day in regard to all matters connected with horsemanship. To Capt. Hayes are also due the excellent photographs by which the book is illustrated, showing almost every turn and stroke in a rather complicated game."—Graphic.

FRIEDBERGER and FRÆHNER'S

VETERINARY PATHOLOGY.

Translated from the original German of the recently-published FOURTH EDITION, and Annotated

By Capt. M. H. HAYES, F.R.C.V.S.,

Author of "Points of the Horse," etc. [In the Press.]

Author of "Veterinary Notes for Horse Owners," "Training and Horse Management in India," etc., etc.

Imperial 16mo. 12s. 6d.

A Natural History of the Mammalia of India, Burmah, and Ceylon.

By R. A. Sterndale, F.R.G.S., F.Z.S., etc.,

With 170 Illustrations by the Author and Others.

"It is the very model of what a natural history should be."—Knowledge.
"An amusing work with good illustrations."—Nature.
"The results of a close and sympathetic observation."—Athenaeum.
"The notices of each animal are, as a rule, short, though on some of the larger mammals—the lion, tiger, pard, boar, etc.—ample and interesting details are given, including occasional anecdotes of adventure. The book will, no doubt, be especially useful to the sportsman, and, indeed, has been extended so as to include all territories likely to be reached by the sportsman from India. Those who desire to obtain some general information, popularly conveyed, on the subject with which the book deals, will, we believe, find it useful."—The Times.
BEHIND THE BUNGALOW.

By EHA,

Author of "The Tribes on My Frontier." With Fifty-three Clever Sketches by the Illustrator of "The Tribes."

As "The Tribes on my Frontier" graphically and humorously described the Animal Surroundings of an Indian Bungalow, the present work describes with much pleasure the Human Officials thereof, with their peculiarities, idiosyncrasies, and, to the European, strange methods of duty. Each chapter contains Character Sketches by the Illustrator of "The Tribes," and the work is a "Natural History" of the Native Tribes who in India render us service.

"'The Tribes on my Frontier' was very good; 'Behind the Bungalow' is even better. Anglo-Indians will see how truthful are these sketches. People who know nothing about India will delight in the clever drawings and the truly humorous descriptions, and, their appetite for fun being gratified, they will not fail to note the undercurrent of sympathy."—The Graphic.

"They show through all their fun a keen observation of native character and a just appreciation of it."—The World.

THE TRIBES ON MY FRONTIER.

By EHA.

With Fifty Illustrations by F. C. MACRAE.

Not this remarkably clever work there are most graphically and humorously described the animal surroundings of a Mofussil bungalow. The twenty chapters embrace a year's experiences, and provide endless sources of amusement and suggestion. The numerous able illustrations add very greatly to the interest of the volume, which will find a place on every table.

"Delightful book."—Knowledge.

"Always amusing, never dull."—Field.

"Pleasantly written."—Graphic.

"May he live to give us another such."—Chambers' Journal.
New Work by EHA, Author of "The Tribes on My Frontier" and "Behind the Bungalow."

**A NATURALIST on the PROWL.**

Illustrated by 80 Drawings by R. A. STERNDALE, F.R.G.S., F.Z.S.,

*Author of "Mammalia of India," "Denizens of the Jungle," "Seonee," &c., who has studied and sketched animals of all kinds in their habitat and at work.*

"It is one of the most interesting Books upon Natural History that we have read for a long time. It is never dull, and yet solid information is conveyed by nearly every page."—Daily Chronicle.

**LARGE GAME SHOOTING**

In Thibet, the Himalayas, Northern and Central India.

By Brig.-General

ALEX. A. A. KINLOCH.

"Colonel Kinloch, who has killed most kinds of Indian game, small and great, relates incidents of his varied sporting experiences in chapters, which are each descriptive of a different animal. The photogravures of the heads of many of the animals, from the grand gaur, popularly called the bison, downwards, are extremely clever and spirited."—Times.

"Splendidly illustrated record of sport."—Graphic.
LAYS OF IND.

By ALIPH CHEEM.

Comic, Satirical and Descriptive Poems illustrative of English Life in India.

"Highly amusing ballads and songs, which have already in a former edition warmed the hearts and cheered the lonely hours of many an Anglo-Indian, the pictures being chiefly those of Indian life. There is no mistaking the humour, and at times, indeed, the fun is both fast and furious. One can readily imagine the merriment created round the camp fire by the recitation of 'The Two Thumpers,' which is irresistibly droll. . . . The edition before us is enlarged, and contains illustrations by the author, in addition to which it is beautifully printed and handsomely got up, all which recommendations are sure to make the name of Aliph Cheem more popular in India than ever."—Liverpool Mercury.

DEPARTMENTAL DITTIES

AND OTHER VERSES.

Being Humorous Poems of Anglo-Indian Official Life.

By RUDYARD KIPLING,

Author of "Plain Tales from the Hills," "Barrack Room Ballads," "The Light that Failed," etc.

"They reflect with light gaiety the thoughts and feelings of actual men and women, and are true as well as clever. . . . Mr. Kipling achieves the feat of making Anglo-Indian society flirt and intrigue visibly before our eyes."—Sir W. H. Hunter in The Academy.
ECH0ES FROM OLD CALCUTTA.

By H. E. BUSTEED, C.I.E.

A most interesting Series of Sketches of Calcutta Life, chiefly towards the close of the last Century, embracing the Capture of Calcutta—the Black Hole—Sir Philip Francis—Nuncomar—First Indian Newspaper—Madame Grand—Warren Hastings, etc.

"Dr. BUSTEED has unearthed some astonishing revelations of what European Life in India resembled a century back. Perhaps for the first time has the Black Hole drama been told in a way fully to bring home to the mind the appalling nature of the sufferings undergone by our countrymen and countrywomen."—Daily Telegraph.

Hindu Mythology:

VEDIC AND PURANIC.

By Rev. W. J. WILKINS,
OF THE LONDON MISSIONARY SOCIETY, CALCUTTA.

Illustrated by One Hundred Engravings, chiefly from Drawings by Native Artists.

"His aim has been to give a faithful account of the Hindu deities such as an intelligent native would give, and he has endeavoured, in order to achieve his purpose, to keep his mind free from prejudice or theological bias. To help to completeness he has included a number of drawings of the principal deities, executed by native artists. The author has attempted a work of no little ambition and has succeeded in his attempt, the volume being one of great interest and usefulness; and not the less so because he has strictly refrained from diluting his facts with comments of his own. It has numerous illustrations."—Home News.

"Mr. Wilkins has done his work well, with an honest desire to state facts apart from all theological prepossession, and his volume is likely to be a useful book of reference."—Guardian.
